Abstract

We relate the Factor-Mimicking Portfolio (FMP) to the beta-pricing model and propose that FMP should jointly minimize the mispricing component of stock returns with respect to the underlying factor. We also study the methodological issues for FMP construction when the underlying factor contains a noise component, and offer a new method to resolve these issues. To examine classical as well as newly proposed method, we recommend enhanced necessary criteria. FMPs of several macroeconomic factors constructed by our method satisfy the criteria. We find that equity returns are priced by consumption growth, inflation, and the unemployment rate; and corporate bond returns are priced by consumption growth, industrial production, and the default spread.

Key words: Factor-mimicking Portfolios, Non-traded Factors, Risk Premium

JEL classification: G10, G12, G11

1. Introduction

Perhaps the most important question in asset pricing is whether different average returns across assets are rewarded for risk. Firm characteristics, such as size, book-to-market ratio, momentum, investment, and profitability, are related reliably to cross-sectional differences in asset returns (Fama and French (1993, 2016, 2018a); Hou, Xue, and Zhang (2015)). However, whether they proxy for risk exposures still needs to be determined (Pukthuanthong, Roll, and Subrahmanyam, (2019)).

Theoretically, macroeconomics factors (e.g., Chen, Roll and Ross (1986)) and other non-traded factors (e.g., Adrian, Etula and Muir (2014)) capture the fundamental risks in the economy and thus should also explain the cross-sectional expected returns. However, observed changes in these factors contain measurement error and have a weak prediction for asset returns. In an effort to reduce the factor noise, previous literature (Huberman, Kandel, and Stambaugh (1987), Breeden, Gibbons and Litzenberger (1989), Ferson, Siegel and Xu (2006), Balduzzi and Robotti (2008), Giglio and Xiu (2018)) recommends factor-mimicking portfolios (FMPs), which is a portfolio representation of the underlying non-traded factor. The extant literature often applies FMPs for testing asset pricing models (e.g., Cooper and Priestley (2011), Barillas et al. (2019), Pukthuanthong et al. (2019)). [1]

Following Huberman, Kandel, and Stambaugh (1987) and Breeden, Gibbons, and Litzenberger (1989), an FMP is chosen to maximize the correlation with the underlying factor (maximum correlation portfolio). In this paper, we provide a new theory of the FMP. Specifically, the factor mimicking portfolio is selected to jointly minimize the mispricing component of stock returns with respect to the underlying factor, with the constraint that the covariance of any test asset return with the underlying factor is the same as that with FMP return. In other words, among the portfolios that represent the underlying factor risk, the least mispriced portfolio is selected. Through the least mispriced portfolio, we link the FMP construction with the beta pricing model, while the maximum correlation portfolio is built on mean-variance efficiency. Thus, the connection between the two

[1] The other applications are pointed out by Roll and Srivastava (2018, p. 21), "mimicking portfolios have many potential uses, including (though not limited to): (1) Evaluating active manager performance, (2) Substituting for a desired investment in illiquid assets, (3) Determining the true potential for improved diversification, (4) Understanding the sources of past return volatility, (5) Predicting the likely level of future return volatility."

theories is based on the equivalence between the beta pricing model and the mean-variance efficiency.

Least mispricing theory suggests several different methods to construct FMPs. The first method is based on Lehmann and Modest (1988, henceforth LM) who apply the WLS Fama-Macbeth (1973) cross-sectional regressions and then use the time series of estimated coefficients in the second-pass regression as FMPs. A simplified OLS cross-sectional method is also widely used. The second is the time-series approach where contemporaneous returns of basis assets are regressed on non-traded factors. Lamont (2001) is one of the leading papers using this approach to construct FMPs from 13 basis assets, which are portfolios formed by sorting individual firm characteristics. The third approach is the sorting-by-beta approach where stocks are sorted into portfolios according to their factor loadings (betas). Then, a long-short portfolio between top and bottom deciles is used as FMPs.

Empirically, constructed FMP suffers methodological issues, when the underlying factor contains measurement error, and when there are multiple correlated risk factors to price asset returns. For example, with the cross-sectional approach,[2] we show that, by controlling the other factors, the constructed FMP is a combination of the underlying factor and the controlling factors; thus, it does not represent the underlying factor alone (we call it "factor contamination"). This apparently surprising result is due to the interaction between the variance of measurement error and the covariance between the underlying and controlling factors. Instead, we show that applying the cross-sectional method without controlling other factors does not suffer the factor contamination issue. That is, the first methodological contribution is to use single factor model for FMP estimation.

The cross-sectional method also suffers the Errors-in-Variables (EIV) issue. To correct it, our first enhanced approach relies on instrumental variable (IV) estimation with individual equities following Jegadeesh et al. (2019). We divide the entire sample into even and odd month subsamples and estimate betas in each subsample separately. Then, betas from the even-month subsample act as instrumental variables for the betas from odd months, or vice versa, in cross-sectional IV regressions with individual stock returns as the dependent variable. Stein (1956)

[2] We also examine the issues for time-series and sorting-by-beta approaches, which are similar to those for cross-sectional method.

introduces a shrinkage method to reduce the root-mean-square error. We also examine these two alternative approaches for FMP construction.

FMP is applied in testing asset pricing models. Given that it is the excess return, its average value is the risk premium estimate (one-stage method). Another method is to reapply cross-sectional regression to estimate the risk premium using FMPs as factors (two-stage method). We show that in the finite sample, the one-stage method leads to noisier risk premium estimates for factors with large measurement error. Hence, two-stage method should be applied.

Basis asset selection can be important in FMP construction. However, different research papers create FMPs from various candidate assets.[3] To avoid arbitrary basis asset selection, we propose to use a large number of test assets (preferable individual stocks/bonds). However, Gospodinov, Kan, and Robotti (2018) show that including uncorrelated assets can affect the inference of asset pricing test. To mitigate this issue, we further suggest variable selection criteria to exclude uncorrelated assets.

Our simulations show that the FMP constructed following the approach proposed above (we call it IV single factor approach, and short it as IV approach) can correctly represent the underlying factor. We find that the correlation between the IV FMP and non-traded factor is nearly one. However, the correlation between FMP constructed by OLS approach with controlling factors (henceforth OLS approach) and the underlying factor is close to 0.8, which is significantly smaller. The correlation is similar or even smaller for other existing methods. Moreover, IV FMP of an underlying factor is not correlated with other uncorrelated risk factors, while FMPs constructed by

[3] Lamont (2001) proposes economic tracking portfolios using 13 basis assets that include eight industry-sorted stock portfolios, four bond portfolios, and a stock market return. Vassalou (2003) uses six equity portfolios sorted by size and book-to-market, term spread and default spread. Aretz (2011) uses a market portfolio, long and intermediate-term government bond portfolios, high-yield corporate bonds and gold. Kroencke et al. (2013) use equity portfolios sorted by size and book-to-market, and a momentum portfolio. Bianchi et al. (2017) use six size and book-to-market sorted portfolios, plus the default and term spreads. Barillas et al. (2017) use 15 traded factors as basis assets. Maio (2018) uses the excess market return, value spread, term spread and S&P 500 price-to-earnings ratio. With the cross-sectional approach, Lehmann and Modest (1988) use size, dividend yield and variance sorted portfolios, and Cooper and Priestley (2011) use 40 portfolios sorted by size, book-to-market, momentum, and asset growth. Pukthuanthong et al. (2019) use 50 portfolios sorted by size, book-to-market, momentum, investment and operating profitability. Roll and Srivastava (2018) use eight ETF portfolios.

other methods are correlated with them, suggesting that only IV FMP is not contaminated by other factors.

We evaluate existing and newly introduced approaches to construct FMP and test underlying factors. We propose the examination should hinge on the following criteria:

(1) FMPs are correlated with the underlying factors,

(2) FMPs are correlated with the systematic risk of returns,

(3) FMPs explain the cross-sectional of mean returns.

Intuitively, an FMP should be a proxy for the risk of the underlying factor; therefore, (1) should be satisfied. Besides, if the underlying factor is a true pricing factor that reflects asset risk, an FMP should represent systematic risk and price assets cross-sectionally ((2) and (3) should be satisfied).

The criteria are examined in real data. For criteria (1), we estimate the correlations between FMPs and underlying factors. We find that the correlation between the FMP return and the underlying factor using the IV approach is smaller than that using the OLS approach. However, we show that the higher correlation of the OLS can be driven by the Errors-in-Variables issue presented in FMP. Therefore, the neoclassical criteria for creating the empirical maximum correlation portfolio, which is the FMP created by OLS method, can be misleading, especially for weak macroeconomic factors in which the EIV bias is relatively large. We also find that the above correlation for the IV approach is larger than that for the time-series approaches. Across subperiods, the times-series approaches cannot produce significant correlation, while the cross-sectional approaches can.

We also examine criteria (2) following Pukthuanthong, Roll, and Subrahmanyam (2019), in which they propose that a genuine risk factor must be related to the systematic risks (proxied by the covariance matrix of returns). We find that for cross-sectional approaches, most of the FMPs represent the systematic risk of stocks. However, for the time-series approach, the FMPs fail to consistently deliver a systematic risk.

For criteria (3), our empirical results reveal that IV-constructed FMPs yield more significant risk premiums. For example, the monthly risk premium for the FMP of consumption growth constructed with the IV approach is 0.164%, while the risk premium of the OLS method is 0.066%. The significance level increases from 5% to 1%. We also find that FMPs for the unemployment rate and CPI contain significant risk premia when they are constructed with IV, but not when obtained via other approaches. The Lehmann and Modest (1988), and Stein methods yield more significant risk premia than OLS, but not as significant as IV. Risk premiums estimated by the Lamont (2001) and sorting-by-beta approaches are in general insignificant. To study the robustness of consumption growth, we also include the CAY (the log of the consumption to wealth ratio) factor by Lettau and Ludvigson (2001) and the consumption volatility factor by Boguth and Kuehn (2013), but they deliver little incremental power to consumption growth.

We also construct FMPs from various approaches for non-traded factors to price individual corporate bonds. The only cross-sectional approach of FMP construction that passes all three criteria is the IV approach. Using the IV, we find that consumption growth, industrial production, bond market factors, and the default spread are associated with significant and positive risk premiums.

Our contribution is fourfold. First, we provide a new economic interpretation for the factor-mimicking portfolio, in addition to maximal correlation portfolio proposed by Breeden, Gibbons, and Litzenberger (1979), and Huberman, Kandel, and Stambaugh (1987). We also examine the relation between the two theories.

Second, we propose new methods for constructing FMPs. In simulations, we find that the IV approach yields perfect proxy for the risk component of non-traded factors. In contrast, previous cross-sectional approaches such as OLS, Lehmann, and Modest (LM) (1988), Stein's approach and Thiel' approach, as well as sorting-by-beta and time-series approaches are subject to substantial factor contamination.

Third, we propose three selection criteria for examining factor-mimicking portfolios. For example, instead of maximizing the correlation between the FMP and the underlying factor, our analogous but revised criterion is that an effective FMP should have significant, but not maximum, correlation with its underlying risk factor. This is to avoid inflated correlation in the presence of estimation error.

Fourth, we sponsor a horserace among the IV approach and other approaches in both the stock and bond markets. We find that IV is the winning horse for traded versions (FMPs) of macroeconomic factors, including consumption growth, the CPI, unemployment, and default spread. FMPs constructed with IV satisfy three criteria: they are correlated with the underlying factors, associated with the systematic risk in asset returns, and unlike the alternative approaches, have large and significant risk premiums in both equity and bond markets.

Our paper is related to Balduzzi and Robotti (2008) who conclude that using time-series formulation of FMPs performs better in term of estimating risk premia than using the original factors with one-step cross-sectional approach. We provide a possible explanation for their findings since the finite sample error is much larger for one-step cross-sectional approach. Kleibergen and Zhan (2018) propose a test of the risk premia of FMPs constructed by a time-series approach that does not depend on the magnitude of betas. However, their approach focuses more on inference and suffers information lost through their portfolio construction. Rather than constructing mimicking portfolios for factors, Roll and Srivastava (2018) construct mimicking portfolios for individual stocks returns but using a cross-sectional OLS approach. Fama and French (2018b) construct mimicking portfolios for characteristics using cross-sectional approach and find that these characteristic-mimicking portfolios have better explanatory power to average return than sorting-characteristic based factors (such as SMB, HML, etc.). We focus on non-traded factor, especially macroeconomic factors in this paper. Instead of using FMPs, Kleibergen, and Zhan (2019 forthcoming) extend the Gibbons-Ross-Shanken statistic to identify the risk premia of macro-risk factors, and also discover significant risk premium for consumption growth.

Section 2. The least mispriced portfolio and its relation to the maximum correlation portfolio

This section proposes a new economic theory of a factor mimicking portfolio (FMP). We also connect this new theory to maximum correlation theory. Although the economic interpretations are different, the two theories lead to the same FMP formula. We discuss the economic reason for the equivalence between these two theories. And we also derive three different methods to construct FMPs based on the new theory.

Section 2.1. The least mispriced portfolio theory

The FMP is constructed by minimizing the mispriced component of asset returns. Let N denote the number of test assets. Let $\boldsymbol{R} = [R^1, \cdots, R^N]$,[4] an N by 1 vector, denote their excess returns. Let a non-traded factor be $\tilde{f}$.[5] The factor can be decomposed as $\tilde{f} = f + \varepsilon_f$, where f is its projection into the excess return space (i.e., there is a linear combination of excess returns that is equal to f), and ε_f is the measurement error, with mean zero and $cov(\varepsilon_f, \boldsymbol{R}) = 0$. We assume that the excess returns depend linearly on the projected factor f,

$$\boldsymbol{R} = \boldsymbol{\alpha} + \boldsymbol{\beta} f + \boldsymbol{\varepsilon}\,. \tag{1}$$

Here, $\boldsymbol{\beta}$ (N by 1) is the factor loading, $\boldsymbol{\alpha}$ (N by 1) is the mispricing component, $\boldsymbol{\varepsilon}$ is the residual of the pricing model, and its variance is denoted $\boldsymbol{\Omega}$. Also, we assume that $\tilde{f}$ contains only one factor; therefore, it is possible that the residual, $\boldsymbol{\varepsilon}$, can be correlated with other factors.[6] Our goal is to select a factor mimicking portfolio that can minimize the mispricing of the asset pricing model. The minimization problem can be written as follows:

$$\min_{\boldsymbol{w}} \boldsymbol{\alpha}'\boldsymbol{\Sigma}\boldsymbol{\alpha} \text{ subject to } cov(\boldsymbol{w}'\boldsymbol{R}, \boldsymbol{R}) = cov(\tilde{f}, \boldsymbol{R}). \tag{2}$$

Here $\boldsymbol{w}$ (N by 1) represents the weight of the portfolio, and the weighting matrix, $\boldsymbol{\Sigma}$ (N by N), is used to control the relative importance of the mispricing components across assets.

Note that the constraint in the minimization problem requires that for any asset, the covariance between the mimicking portfolio and the asset's return is the same as the covariance between the factor and the asset's return, i.e., the factor's volatility is the same as that of the mimicking portfolio. Since f is the projection of the non-traded factor, the constraint (2) also implies that the portfolio return is equal to f, i.e.

$$\boldsymbol{w}'\boldsymbol{R} = f.$$ [7]

[4] Note that each entry of $\boldsymbol{R}$ is a random variable, representing the return of each asset. In latter section, we will use $\boldsymbol{\mathfrak{R}}$, a T by N matrix, to represent the matrix of time-series realization of N assets.

[5] Note that $\tilde{f}$ is a random variable. In the latter sections, we use the notation $\tilde{\boldsymbol{f}} = [\tilde{f}_1, \cdots, \tilde{f}_T]'$, a T by 1 vector, to represent the time-series realization of the non-traded factors. This convention is applied to all random variables defined in this paper.

[6] With this assumption, we extract the largest component of the return that is correlated with the factor, regardless of the existence of other factors.

[7] From $cov(\boldsymbol{w}'\boldsymbol{R}, \boldsymbol{R}) = cov(\tilde{f}, \boldsymbol{R}) = cov(f, \boldsymbol{R})$, thus $cov(\boldsymbol{w}'\boldsymbol{R} - f, \boldsymbol{R}) = cov(\boldsymbol{w}'\boldsymbol{R}, \boldsymbol{R}) - cov(f, \boldsymbol{R}) = 0$. Since $\boldsymbol{w}'\boldsymbol{R} - f$ is in the excess return space, there is a linear combination of returns (denoted by $\boldsymbol{\pi}'\boldsymbol{R}$) that is equal to $\boldsymbol{w}'\boldsymbol{R} - f$. Thus, the equation $cov(\boldsymbol{w}'\boldsymbol{R} - f, \boldsymbol{R}) = 0$ implies that $var(\boldsymbol{w}'\boldsymbol{R} - f) = cov(\boldsymbol{w}'\boldsymbol{R} - f, \boldsymbol{w}'\boldsymbol{R} - f) = cov(\boldsymbol{w}'\boldsymbol{R} -$

With the above equation, $\boldsymbol{\alpha} = E(\boldsymbol{R}) - \boldsymbol{\beta}E(f) = E(\boldsymbol{R}) - \boldsymbol{\beta}E(\boldsymbol{w}'\boldsymbol{R})$. Therefore, the objective function can be written as follows:

$$\min_{\boldsymbol{w}} \boldsymbol{\alpha}'\boldsymbol{\Sigma}\boldsymbol{\alpha} = \left(E(\boldsymbol{R}) - \boldsymbol{\beta}E(\boldsymbol{w}'\boldsymbol{R})\right)'\boldsymbol{\Sigma}(E(\boldsymbol{R}) - \boldsymbol{\beta}E(\boldsymbol{w}'\boldsymbol{R})). \tag{3}$$

In the following proposition, we derive the solution to the above minimization problem.

Proposition 1: Let the scaled weight $\boldsymbol{w_s} = \frac{\boldsymbol{w}}{var(\boldsymbol{w}'\boldsymbol{R})}$. The optimum weight solution to the minimization problem (1) can be written as, $\boldsymbol{w_s^*} = \frac{(cov(f,\boldsymbol{R}))'\boldsymbol{\Sigma}E(\boldsymbol{R})}{(cov(f,\boldsymbol{R}))'\boldsymbol{\Sigma}(cov(f,\boldsymbol{R}))} E(\boldsymbol{R})(E(\boldsymbol{R})'E(\boldsymbol{R}))^{-1}$. Hence, the expected portfolio return is

$$E(\boldsymbol{R})'\boldsymbol{w_s^*} = \frac{(cov(f,\boldsymbol{R}))'\boldsymbol{\Sigma}E(\boldsymbol{R})}{(cov(f,\boldsymbol{R}))'\boldsymbol{\Sigma}(cov(f,\boldsymbol{R}))}. \tag{4}$$

The proof is in the appendix. Given that the portfolio can minimize the mispricing component of the test assets, we call it the least mispriced portfolio. Since $\boldsymbol{\beta} = \frac{cov(f,\boldsymbol{R})}{var(f)}$, Equation (4) is equivalent to

$$E(\boldsymbol{R})'\boldsymbol{w_s^*} = \frac{1}{var(f)} \frac{\boldsymbol{\beta}'\boldsymbol{\Sigma}E(\boldsymbol{R})}{\boldsymbol{\beta}'\boldsymbol{\Sigma}\boldsymbol{\beta}}. \tag{5}$$

From Equation (5), if the cross-sectional expected returns are more correlated with their $\boldsymbol{\beta}$, the numerator in equation (5) is larger. Thus, the optimum portfolio has higher expected returns. Intuitively, $\boldsymbol{\beta}$ reflects the sensitivity of the asset to the factor risk. If a majority part of the cross-sectional variation of asset returns can be explained by this factor, the mispriced component is smaller. Hence, the expected return of the pricing component, which is the left-hand side of the equation (5), should be larger.

Define unit weight as $\boldsymbol{w_u} = \frac{\boldsymbol{w}}{std(\boldsymbol{w}'\boldsymbol{R})}$, and unit factor as $f_u = \frac{f}{std(\boldsymbol{w}'\boldsymbol{R})}$. The equation (4) can also be rewritten as

$f, \boldsymbol{\pi}'\boldsymbol{R}) = 0$. Given that the only random variable in excess return space that has zero variance is zero (if there is another constant number in the excess return space, there will be two different risk-free rates, which is impossible), $\boldsymbol{w}'\boldsymbol{R} - f = 0$.

$$E(\boldsymbol{R})'\boldsymbol{w}_{\boldsymbol{u}}^{*} = \frac{\left(cov(f_u,\boldsymbol{R})\right)'\boldsymbol{\Sigma}E(\boldsymbol{R})}{\left(cov(f_u,\boldsymbol{R})\right)'\boldsymbol{\Sigma}\left(cov(f_u,\boldsymbol{R})\right)}. \tag{6}$$

It is easy to show that the standard deviation of the unit weight portfolio return, $std(\boldsymbol{R}'\boldsymbol{w}_{\boldsymbol{u}}^{*}) = \frac{std(\boldsymbol{R}'\boldsymbol{w})}{std(\boldsymbol{R}'\boldsymbol{w})} = 1$. Hence, Equation (6) represents the expected return of a portfolio with unit risk. Similarly, since the commeasurable component of the factor should be the same as the optimum portfolio,

$$std(f_u) = \frac{std(f)}{std(\boldsymbol{R}'\boldsymbol{w})} = \frac{std(\boldsymbol{R}'\boldsymbol{w})}{std(\boldsymbol{R}'\boldsymbol{w})} = 1.$$

Given that the expected return for a factor mimicking portfolio is also the risk premium of the underlying non-traded factor, the equation (6) also represents the risk premium of the factor with unit risk.

Section 2.2 Relation with the maximum correlation portfolio

Classical factor mimicking portfolio is constructed through maximizing its correlation with the non-traded factor. Breeden, Gibbons, and Litzenberger (1989) and Roll and Srivastava (2018) provide the theoretical framework for maximum correlation portfolio construction. We follow their approach. For a given value of the loading of the risk factor on its mimicking portfolio, β_{fmp} (Normally, β_{fmp} is set to be 1), the variance of the FMP (following the same notation, $\boldsymbol{w}'\boldsymbol{R}$) is reciprocal to the correlation between FMP and $\tilde{f}$, because the variance for factor $(var(\tilde{f}))$ is a constant. The relation can be illustrated by the following formula:

$$\beta_{fmp} = corr\left(\tilde{f}, \boldsymbol{w}'\boldsymbol{R}\right)\frac{\sqrt{Var(\boldsymbol{w}'\boldsymbol{R})}}{\sqrt{Var(\tilde{f})}}. \tag{7}$$

Therefore, maximizing the correlation between FMPs and their underlying factor is equivalent to minimize the variance of the FMPs themselves. Specifically, we want to select the weight for the following minimization problem:

$$\min_{\boldsymbol{w}} \boldsymbol{w}'\boldsymbol{V}\boldsymbol{w} + 2(\beta_{fmp} - \boldsymbol{w}'\boldsymbol{\beta})\,\lambda. \tag{8}$$

where $\boldsymbol{V}$ is the covariance matrix of testing asset returns, and λ is the Lagrange multiplier.

By solving the first-order condition of equation (8), and set β_{fmp} as 1, the optimal weight is

$$\boldsymbol{w}^* = \boldsymbol{V}^{-1}\boldsymbol{\beta}[\boldsymbol{\beta}'\boldsymbol{V}^{-1}\boldsymbol{\beta}]^{-1} . \tag{9}$$

Then the expected return of maximum correlation portfolio can be computed as

$$E(\boldsymbol{R})'\boldsymbol{w}^* = E(\boldsymbol{R})'\boldsymbol{V}^{-1}\boldsymbol{\beta}[\boldsymbol{\beta}'\boldsymbol{V}^{-1}\boldsymbol{\beta}]^{-1}. \tag{10}$$

If we replace $\boldsymbol{\Sigma}$ by $\boldsymbol{V}^{-1}$, equations (5) and (10) are identical, except for scaling in weight ($\frac{1}{var(f)}$). The maximum correlation portfolio coincides with the least mispriced portfolio. The coincidence is not surprising given the equivalence between mean-variance minimization and the Beta-pricing model. If the maximum correlation portfolio of a factor lies on the mean-variance frontier of the test assets (hence the constraint in equation (8) is always binding), the covariance between FMP return ($\boldsymbol{w}'\boldsymbol{R}$) and any asset return is a linear function of its expected return (Cochrane (2005)), i.e.

$$cov(\boldsymbol{w}'\boldsymbol{R}, \boldsymbol{R}) = \gamma_0 + \gamma_1 E(\boldsymbol{R}).$$

Here, γ_0 and γ_1 are constants. Since the $\boldsymbol{w}'\boldsymbol{R}$ and zero beta rate R_0 should also be priced, $var(\boldsymbol{w}'\boldsymbol{R}) = \gamma_0 + \gamma_1 E(\boldsymbol{w}'\boldsymbol{R})$, and $0 = \gamma_0 + \gamma_1 E(R_0)$. Combining these equations, we obtain

$$E(\boldsymbol{R}) - E(R_0) = \frac{cov(\boldsymbol{w}'\boldsymbol{R},\boldsymbol{R})}{var(\boldsymbol{w}'\boldsymbol{R})}\big(E(\boldsymbol{w}'\boldsymbol{R}) - E(R_0)\big) = \boldsymbol{\beta}\big(E(\boldsymbol{w}'\boldsymbol{R}) - E(R_0)\big). \tag{11}$$

Equation (11) implies that the maximum correlation portfolio can correctly price all test assets. Hence, the portfolio is also the least mispriced portfolio (mispricing is zero). When factor misprices some of the assets, its maximum correlation portfolio is not on the mean-variance frontier. The equations (5) and (10) show that the mimicking portfolio that minimizes its variance (closest to the mean-variance frontier) is also the portfolio that minimizes the mispricing component of the beta-pricing model.

Section 2.3 Implied methodology for FMP construction

Both maximum correlation theory and least mispricing theory imply three construction methods for FMPs. In this section, we describe these methods from the latter theory. From equation (5), portfolio return is $E(\boldsymbol{R})'\boldsymbol{w}_s^* = \frac{1}{var(f)}\frac{\boldsymbol{\beta}'\boldsymbol{\Sigma}E(\boldsymbol{R})}{\boldsymbol{\beta}'\boldsymbol{\Sigma}\boldsymbol{\beta}}$. The expected return ($E(\boldsymbol{R})$) and the factor loading ($\boldsymbol{\beta}$) are known. Therefore, the different methods depend on different choice of weighting matrix $\boldsymbol{\Sigma}$.

Case 1, Time series method. In this case, the weighting matrix is the inverse of the covariance matrix of testing asset returns, i.e., $\boldsymbol{\Sigma} = \boldsymbol{V}^{-1}$. Thus,

$$\left(var(f)\right)^2 \boldsymbol{\beta}'\boldsymbol{\Sigma}\boldsymbol{\beta} E(\boldsymbol{R})'\boldsymbol{w}_s^* = var(f)\boldsymbol{\beta}'\boldsymbol{\Sigma} E(\boldsymbol{R}) = cov(f, \boldsymbol{R})'\boldsymbol{V}^{-1}E(\boldsymbol{R})\ . \tag{12}$$

The left-hand side is a scaled expected return of the least mispricing portfolio. The right-hand side provides the estimation method to calculate the return. Specifically, it can be estimated by regressing the non-traded factor on returns of the test assets:

$$f = a + b\boldsymbol{R} + \boldsymbol{u}. \tag{13}$$

The fitted value of the above time-series regression is $cov(f, \boldsymbol{R})'\boldsymbol{V}^{-1}\boldsymbol{R}$. Take the expected value; it is the same as the right-hand side of the equation (12).

Case 2, cross-sectional method. The weighting matrix can be written as $\boldsymbol{\Sigma} = (\boldsymbol{I} - \boldsymbol{1}(\boldsymbol{1}'\boldsymbol{1})^{-1}\boldsymbol{1}')\boldsymbol{V}^{-1}(\boldsymbol{I} - \boldsymbol{1}(\boldsymbol{1}'\boldsymbol{1})^{-1}\boldsymbol{1}')$, where, $\boldsymbol{I}$ is the N by N identity matrix, and $\boldsymbol{1}$ is an N by 1 vector, with each entry 1. Replacing $\boldsymbol{\Sigma}$ in Equation (5), we obtain:

$$var(f)E(\boldsymbol{R})'\boldsymbol{w}_s^* = \frac{\boldsymbol{\beta}'\left(\boldsymbol{I}-\boldsymbol{1}(\boldsymbol{1}'\boldsymbol{1})^{-1}\boldsymbol{1}'\right)\boldsymbol{V}^{-1}\left(\boldsymbol{I}-\boldsymbol{1}(\boldsymbol{1}'\boldsymbol{1})^{-1}\boldsymbol{1}'\right)E(\boldsymbol{R})}{\boldsymbol{\beta}'(\boldsymbol{I}-\boldsymbol{1}(\boldsymbol{1}'\boldsymbol{1})^{-1}\boldsymbol{1}')\boldsymbol{V}^{-1}(\boldsymbol{I}-\boldsymbol{1}(\boldsymbol{1}'\boldsymbol{1})^{-1}\boldsymbol{1}')\boldsymbol{\beta}} = \frac{\overline{\boldsymbol{\beta}}'\boldsymbol{V}^{-1}\bar{E}(\boldsymbol{R})}{\overline{\boldsymbol{\beta}}'\boldsymbol{V}^{-1}\overline{\boldsymbol{\beta}}}. \tag{14}$$

Here, for any random variable $\boldsymbol{X}$, the notation $\overline{\boldsymbol{X}}$ is the demeaned $\boldsymbol{X}$, where the mean is taken across test assets. The left-hand side of equation (14) still represents the expected return of a scaled least mispricing portfolio. The right-hand side is the coefficient of regressing expected returns on its factor loadings across test assets. Specifically, in the following cross-sectional regression:

$$E(\boldsymbol{R}) = \alpha + \gamma\boldsymbol{\beta} + \boldsymbol{v}, \tag{15}$$

when the estimated coefficient γ based on GLS with weighting matrix $\boldsymbol{V}^{-1}$, takes the same form as the right-hand side of equation (14).

The weighting matrix, in this case, contains the covariance matrix of asset returns. This matrix is more difficult to estimation when the number of test assets is large. A special scenario, in this case, is to set $\boldsymbol{V}^{-1} = \boldsymbol{I}$. The right-hand side of the equation (14) becomes $\frac{\overline{\boldsymbol{\beta}}'\bar{E}(\boldsymbol{R})}{\overline{\boldsymbol{\beta}}'\overline{\boldsymbol{\beta}}}$. This corresponds to the coefficient of regression (15) using OLS. On the other hand, Lehmann and

Modest (1988) suggest using the diagonal matrix, which consists of the residual variances $\mathbf{\Omega^{-1}}$ from the regression (1) to replace $\mathbf{V^{-1}}$.

Case 3, sorting-by-beta method. In this case, the weighting matrix is diagonal. For example, we divide the assets into five groups. For the assets in the group with the lowest factor loadings/beta, the corresponding diagonal element is the negative reciprocal of the beta. For the assets in the group with the highest factor loadings/beta, the corresponding diagonal element is the positive reciprocal of the beta. For assets of all the other three groups, the diagonal elements are zero. Specifically, assume that asset 1 through asset $M = \frac{N}{5}$ are in the group with the smallest beta, and asset $4M + 1$ to asset $5M$ are in the group with the largest beta. Hence, the weighting matrix can be written as $\boldsymbol{\Sigma} = \begin{pmatrix} \boldsymbol{\Sigma_{11}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Sigma_{22}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \boldsymbol{\Sigma_{33}} \end{pmatrix}$, where $\boldsymbol{\Sigma_{11}} = \begin{pmatrix} -\frac{1}{\beta_1} & \cdots & 0 \\ \cdots & \cdots & \cdots \\ 0 & \cdots & -\frac{1}{\beta_M} \end{pmatrix}$, $\boldsymbol{\Sigma_{22}} = \begin{pmatrix} 0 & \cdots & 0 \\ \cdots & \cdots & \cdots \\ 0 & \cdots & 0 \end{pmatrix}$, and $\boldsymbol{\Sigma_{33}} = \begin{pmatrix} \frac{1}{\beta_{4M+1}} & \cdots & 0 \\ \cdots & \cdots & \cdots \\ 0 & \cdots & \frac{1}{\beta_{5M}} \end{pmatrix}$. Replace $\boldsymbol{\Sigma}$ in equation (5),

$$\frac{1}{M} var(f)\boldsymbol{\beta}'\boldsymbol{\Sigma}\boldsymbol{\beta}E(\boldsymbol{R})'\boldsymbol{w}_{\boldsymbol{s}}^{*} = \frac{1}{M}\left(\sum_{i=4M+1}^{5M} E\left(R^i\right) - \sum_{i=1}^{M} E\left(R^i\right)\right). \tag{16}$$

The right-hand side of the equation (16) is the difference between the average expected return of the high beta and low beta groups, which represents another method to calculate the scaled least mispriced portfolio on the left-hand side.

Section 3. Measurement error in factors and econometric issue for FMP construction

We provide methods to construct the least mispriced portfolio in the previous section. Empirically, the measurement error in the non-traded factor leads to issues for these methods. In this section, we discuss these issues and propose an adjustment approach. The focus is on the cross-sectional method, but we will also discuss the bias in the time-series and the sorting-by-beta methods.

Section 3.1 One factor case

In this subsection, we examine the simple case when asset returns depend only a single factor, which is non-traded. Following the notation in the previous section, the non-traded factor including measurement error is denoted by $\tilde{f}$, f is its component related to returns, and ε_f is the measurement error. The FMP is constructed by the two-pass cross-sectional method. For a sample period of length T periods, let R_t^i be the return of asset i at time t, $\tilde{f}_t$ be the factor at time t. Define $\boldsymbol{R}^i = [R_T^i, \cdots, R_T^i]'$, and $\tilde{\boldsymbol{f}} = [\tilde{f}_1, \cdots, \tilde{f}_T]'$. The first pass estimates betas by running a time-series regression for each asset:

$$\boldsymbol{R}^i = \alpha^i + \beta^i \tilde{\boldsymbol{f}} + \boldsymbol{\varepsilon}^i, \tag{17}$$

where α^i and β^i are regression coefficients, and $\boldsymbol{\varepsilon}^i = [\varepsilon_T^i, \cdots, \varepsilon_T^i]'$ is the regression residual. The second pass is a cross-sectional regression at each time point t (for $t \in \{1,2,\cdots,T\}$). Define $\boldsymbol{R_t} = [R_t^1, \cdots, R_t^N]$ and $\boldsymbol{\beta} = [\beta^{\boldsymbol{1}}, \cdots, \beta^{\boldsymbol{N}}]$. The regression can be written as:

$$\boldsymbol{R_t}' = a_t + \lambda_t \widehat{\boldsymbol{\beta}}' + \boldsymbol{\eta_t}. \tag{18}$$

Here, we use $\widehat{\boldsymbol{\beta}}$ to represent the estimated value of the factor loading β^i, and residual $\boldsymbol{\eta_t} = [\eta_t^1, \cdots, \eta_t^N]$. The estimated coefficient λ_t, is the return for the FMP at time t.

The key difference between equations (17) and (18) and the cross-sectional regression on traded factors is that $\tilde{f}$ contains measurement error. With some mild regularity conditions on measurement error ε_f, as well as the factor and regression residuals, the next proposition shows that the FMP constructed by the two-pass method can adjust for the measurement error.

Proposition 2: Assume that (1) measurement error ε_f are uncorrelated with R^i for any asset i, uncorrelated with f and uncorrelated with regression residual ε^i, (2) Regression residuals are uncorrelated with factors f, (3) beta ($\boldsymbol{\beta}$) is uncorrelated with the cross-sectional regression errors ($\boldsymbol{\eta_t}$). As sample period T converges to infinity, the estimated coefficient λ_t converges to $c(f_t - E(f) + \gamma)$, where γ is the factor risk premium, and $c = (var(f) + var(\varepsilon_f))/var(f)$ is a constant.

The proof is in the appendix. This is also shown in section 6.2 of Balduzzi and Robotti (2008). From the proposition, the estimated coefficient is a linear transformation of the factor without measurement error.[8] In particular, the FMP is scaled by a constant c. Intuitively, the measurement

[8] When there is no measurement error ($\varepsilon_f = 0$), The factor at time t is f_t. Hence, the estimated coefficient in proposition 2 ($c(f_t - E(f) + \gamma)$) is a linear transformation of the factor without measurement error.

error in the non-traded factor leads to a scaling effect in the estimated beta coefficient in the first pass. But beta (which is the independent variable for the second pass regression) for all stocks are scaled by the same constant. Thus, the estimated coefficient in the second pass cross-sectional regression is also scaled.

Moreover, from proposition 2, the scaling effect on λ_t is homogeneous across time (by a constant number c). Thus, the scaled FMP can still represent the same factor in asset pricing test. To test for a significant risk premium, we can calculate the average value of the coefficients over time as the risk premium estimates and calculate the Fama-Macbeth standard deviation of the regression coefficients, i.e. the average value of coefficients is $\frac{1}{T}\sum_{t=1}^{T} c(f_t - E(f) + \gamma)$, and the Fama-Macbeth standard deviation of the coefficients is the sample standard deviation of $c(f_t - E(f) + \gamma)$. Both the average and standard deviation are scaled by the same constant number. When the sample size is large and true risk premium is zero (Null hypothesis), the T-stats formed by the estimates and the standard deviation above is not affected by the constant number and converges to a standard normal distribution. In Section 3.5, we introduce the two-stage regression method (rerun Fama-Macbeth method on λ_t for another time) to estimate the risk premium. In both testing methods, T-stats are not affected by the constant c because the estimated risk premium and its standard deviation are both multiplied by the number. [9]

Section 3.2 Bias in FMP when there is a correlated factor

Although the cross-sectional method for the one-factor model can remove the measurement error and create an FMP that represents the risk of a single factor, there could be several factors and they could be correlated. Theoretically, to separate the effect of the interested factor (the non-traded factor) on asset returns and construct an FMP, it is natural to control other factors. However, with the measurement error in the non-traded factor, even after controlling for other factors, the proposition below shows that the FMP will still contain a component from these other factors, which is not a desirable quality in an FMP.

To simplify without loss of generality, we assume that there are two factors (the two-factor assumptions apply throughout the analysis in subsections 3.2-3.4), $\tilde{f}_1$ and f_2. Factor 1 has

[9] In finite sample, there is an EIV issue that comes from the error in the estimated beta. This EIV issue can lead to a bias T-stats. We will discuss this issue and corresponding method to mitigate it in section 3.6.

measurement error denoted by ε_{f_1}.[10] Moreover, assume that two factors are correlated, i.e., $cov(f_1, f_2) \neq 0$. With the same vector notation in section 3.1, the true regression model can be written as

$$\boldsymbol{R^i} = \alpha^i + \beta_1^i \boldsymbol{f}_1 + \beta_2^i \boldsymbol{f}_2 + \boldsymbol{\varepsilon}^i. \tag{19}$$

If factor 1 has a measurement error, we have to replace $\boldsymbol{f}_1$ by $\tilde{\boldsymbol{f}}_1$, its observed version before being able to run regression (19.) Then with the resulting estimated beta coefficients, we compute the following cross-sectional regression:

$$\boldsymbol{R}_t{}' = \alpha_t + \lambda_{1t}\boldsymbol{\beta}_1{}' + \lambda_{2t}\boldsymbol{\beta}_2{}' + \boldsymbol{\eta_t}. \tag{20}$$

Proposition 3: In first pass regression (19), with observed factor 1, assume that measurement error is uncorrelated with asset returns, regression residuals, and both factors, the regression residuals are also uncorrelated with both factors, and the betas are uncorrelated with the cross-sectional regression errors.

(A) When sample size T converges to infinity,

$$\hat{\beta}_1^i \to \frac{var(f_1)var(f_2) - cov(f_1, f_2)^2}{DET_1}\beta_1^i \equiv B_1^i, \text{ and } \hat{\beta}_2^i \to \beta_2^i + \frac{var(\varepsilon_{f_1})(\beta_1^i cov(f_1, f_2) + \beta_2^i var(f_2))}{DET_1} \equiv B_2^i, \tag{21}$$

where $DET_1 = \left(var(f_1) + var\left(\varepsilon_{f_1}\right)\right) var(f_2) - cov(f_1, f_2)^2$.

In second pass regression (20),

(B) when both T and N (the number of test assets) converge to infinity,

$$\hat{\lambda}_{1t} \to w_1\gamma_{1t} + w_2\gamma_{2t}, \tag{22}$$

where

$$w_1 = \frac{1}{DET_2}\frac{var(f_1)var(f_2) - cov(f_1, f_2)^2}{DET_1}\left(\overline{var}\left(B_2^i\right)\overline{var}\left(\beta_1^i\right) - \overline{cov}\left(\beta_1^i, B_2^i\right)\right)$$

$$w_2 = \frac{1}{DET_2}\frac{var(f_1)var(f_2) - cov(f_1, f_2)^2}{DET_1}\left(\overline{var}\left(B_2^i\right)\overline{cov}\left(\beta_1^i, \beta_2^i\right) - \overline{cov}\left(\beta_1^i, B_2^i\right)\overline{cov}\left(\beta_2^i, B_2^i\right)\right)$$

[10] We assume there is no measurement error for the second factor (i.e. they can be traded factors) to simplify the analysis. We obtain a similar format to equation (22) when measurement error is included.

$$DET_2 = \overline{var}(B_1^i)\overline{var}(B_2^i) - \overline{cov}(B_1^i, B_2^i)^2$$

$$\gamma_{1t} = f_{1t} - E(f_1) + \gamma_1$$

$$\gamma_{2t} = f_{2t} - E(f_2) + \gamma_2.$$

Here, $\overline{var}$ and $\overline{cov}$ are the cross-sectional variance and covariance. We use the upper bar to distinguish it from their time-series companions. Moreover, γ_1 and γ_2 are the risk premium of factors 1 and 2.

(C) If $cov(f_1, f_2) = 0,\ w_2 = 0$.

The proof is in the appendix. From Equation (21) in proposition 3 (A), the estimated beta for factor 2 is related to the beta of factor 1. Moreover, when we employ the estimated betas in the cross-sectional regression, Equation (22) in proposition 3 (B) shows that the constructed factor mimicking portfolio for factor 1 is also affected by factor 2. In this case, the FMP contains an additional component from factor 2; thus, its risk premium reflects the excess returns associated with a combination of the two risk factors. We call it factor contamination, and it is not a desirable property for an FMP. In conclusion, we cannot construct a pristine FMP using the cross-sectional method by controlling other correlated risk factors.

When the factors 1 and 2 are uncorrelated, from proposition 3 (C) and Equation (22), the FMP of factor 1 does not depend on factor 2. In general, we should not presume that factors 1 and 2 are not correlated. However, if one can create a modified factor 2 that that is uncorrelated with factor 1, and use it as a new factor 2 in FMP construction, the resulting FMP will have the desirable property to represent the risk for the factor 1 only. One classical approach to construct two uncorrelated factors is to remove the effect of factor 1 from factor 2 and to use the remaining component of factor 2 (which is uncorrelated with factor 1) as the control. Specifically, in a regression of factor 2 on factor 1, the regression residual, being orthogonal to factor 1, can become the new factor 2, to be used to as control in the cross-sectional method. When there is no measurement error in factor 1, this method will work. However, given that factor 1 contains measurement error, the following proposition shows that the residual of factor 2 is still correlated with factor 1. Thus, controlling this residual leads to the same factor contamination problem as in Proposition 3.

Proposition 4: Assume that factors 1 and 2 are correlated. Let $u_{12} = f_2 - \frac{cov(\tilde{f}_1, f_2)}{var(\tilde{f}_1)} \tilde{f}_1$, the residual value of regressing factor 2 on non-traded factor 1, the correlation between u_{12} and f_1 is non-zero.

The proof is in the appendix. In sum, we have shown in this subsection that several classical cross-sectional methods to construct FMP for a non-traded factor are not desirable, as long as there is another risk factor that is correlated with the non-traded factor. In section 3.3, we propose a fix for this problem.

Section 3.3 Proposed method

We propose to construct an FMP using a one-factor cross-sectional regression approach even if there are other correlated risk factors. For the cross-sectional approach, there are two passes. We will present the rationale for using only one factor in each pass.

From Equation (1), by running a single-factor regression, we extract the largest component of return that is correlated with the non-traded factor. Even if there is another risk factor, we should still run the one-factor model to obtain the factor loading. Specifically, with two factors f_1 and f_2, assume that the true regression model follows equation (19). Rewrite the (19), we obtain:

$$\boldsymbol{R^i} = \alpha^i + \beta_1^i \boldsymbol{f}_1 + \beta_2^i \boldsymbol{f}_2 + \boldsymbol{\varepsilon}^i = \alpha^i + \left(\beta_1^i + \beta_2^i \frac{cov(f_1, f_2)}{var(f_1)}\right) \boldsymbol{f_1} + \beta_2^i (\boldsymbol{f_2} - \frac{cov(f_1, f_2)}{var(f_1)} \boldsymbol{f_1}) + \boldsymbol{\varepsilon}^i.$$

Redefine $\boldsymbol{f_1^*} = \boldsymbol{f_1}$, $\boldsymbol{f_2^*} = \boldsymbol{f_2} - \frac{cov(f_1, f_2)}{var(f_1)} \boldsymbol{f_1}$, $\beta_1^{i*} = \beta_1^i + \beta_2^i \frac{cov(f_1, f_2)}{var(f_1)}$ and $\beta_2^{i*} = \beta_2^i$.[11] The regression becomes

$$\boldsymbol{R^i} = \alpha^i + \beta_1^{i*} \boldsymbol{f_1^*} + \beta_2^{i*} \boldsymbol{f_2^*} + \boldsymbol{\varepsilon}^i \tag{23}$$

From the construction, $\frac{cov(f_1, f_2)}{var(f_1)} \boldsymbol{f_1}$ is the largest component of factor 2 that is correlated with factor 1, and $\boldsymbol{f_2} - \frac{cov(f_1, f_2)}{var(f_1)} \boldsymbol{f_1}$ is the uncorrelated component. Hence, $\beta_1^{i*} \boldsymbol{f_1^*}$ (which is the same as $\beta_1^{i*} \boldsymbol{f_1}$) is the largest component of return that is correlated with the factor f_1, and remaining parts $\alpha^i + \beta_2^{i*} \boldsymbol{f_2^*} + \boldsymbol{\varepsilon}^i$ characterizes the mispricing component and the error in equation (1). Besides, it is well-known that the loading of factor 1 in Equation (23) is equivalent to the slope coefficient of the single factor regression,

[11] Hence, $\boldsymbol{f_1^*}$ and $\boldsymbol{f_2^*}$ are uncorrelated.

$$\boldsymbol{R^i} = \alpha^i + \beta_1^{i*}\boldsymbol{f_1^*} + \boldsymbol{\varsigma}^i, \tag{24}$$

with $\boldsymbol{\varsigma}^i = \beta_2^{i*}\boldsymbol{f_2^*} + \boldsymbol{\varepsilon}^i$. Therefore, the factor loading β_1^{i*} should be estimated using the one-factor model even if there is a correlated factor. Note that factor 1 contains measurement errors. Thus, in regression (24), we need to replace $\boldsymbol{f_1^*}$ by its observed version $\boldsymbol{\tilde{f}_1^*}$.

We depend on the following assumption to show the validity of the second pass regression using the one-factor model.

Assumption: When there are large enough number of assets, the factor loadings of two uncorrelated factors are also uncorrelated in cross-section, i.e., for factors 1 and 2 ($\boldsymbol{f_1^*}$ and $\boldsymbol{f_2^*}$) in Equation (23),

$$\overline{cov}(\beta_1^{i*}, \beta_2^{i*}) \to 0, \tag{25}$$

when the number of test assets, N, converges to infinity.

In equation (25), β_1^{i*} and β_2^{i*} represent the sensitivity of the asset i on factor $\boldsymbol{f_1^*}$ and $\boldsymbol{f_2^*}$, respectively

. The assumption implies that for any typical asset that is highly sensitive to factor 1, its sensitivity on factor 2 does not necessary to be high ($\overline{cov}\left(\beta_1^{i*}, \beta_2^{i*}\right) > 0$ in this case) or low ($\overline{cov}\left(\beta_1^{i*}, \beta_2^{i*}\right) < 0$ in this case). When number of assets is large, the group of assets with high factor 1 sensitivity could contain both high-factor-2 sensitive and low-factor-2 sensitive assets. For example, suppose consumption growth ($\boldsymbol{f_1^*}$) and value ($\boldsymbol{f_2^*}$) are uncorrelated risk factors for stocks. We should observe both value and growth firms no matter if the firm is cyclical or defensive. I.e., if two factors represent uncorrelated risks, there should be firms that can represent any combinations of the risk factors, when number of firms are large. On the other hand, if consumption growth and market excess return are highly correlated risk factors, the firms with high/low loading on market return should also have high/low loadings on consumption growth. In section 5, we find that the average absolute correlation among factor loadings of orthogonalized (uncorrelated) factors across all individual stocks is only 8%, and the maximum absolute correlation is about 20%. This seems to be consistent with our assumption.

From Equations (23) and (24), when we run the first pass regression only using consumption growth alone, we produce the same factor loadings by controlling the component of the size factor that is uncorrelated with the consumption. In the second pass, the true model should be

$$\boldsymbol{R_t}' = \alpha_t + \lambda_{1t}\widehat{\boldsymbol{\beta}}_1^{*\prime} + \lambda_{2t}\widehat{\boldsymbol{\beta}}_{\boldsymbol{2}}^{*\prime} + \boldsymbol{\nu_t},$$

where $\lambda_{1t} = f_{1t}^* - E(f_1^*) + \gamma_1^* = f_{1t} - E(f_1) + \gamma_1$ and $\lambda_{2t} = f_{2t}^* - E(f_2^*) + \gamma_2^*$.

When assumption (25) is imposed for uncorrelated factors $\boldsymbol{f_1^*}$ and $\boldsymbol{f_2^*}$, and if we run one-factor cross-sectional regression as follows:

$$\boldsymbol{R_t}' = \alpha_t + \lambda_{1t}\widehat{\boldsymbol{\beta}}_1^{*\prime} + \boldsymbol{\eta_t}, \tag{26}$$

Proposition 5 shows that the estimated coefficient in this regression is a linear transformation of f_1.

Proposition 5: Assume that Equation (25) holds. If the measurement error is uncorrelated with asset returns, regression residuals, and both factors, the regression residuals are also uncorrelated with both factors, and the betas are uncorrelated with the cross-sectional regression errors, the estimated coefficient from the model (26),

$$\hat{\lambda}_{1t} \rightarrow c(f_{1t} - E(f_1) + \gamma_1),$$

where $c = (var(f_1) + var(\varepsilon_{f_1}))/var(f_1)$, as sample period T and number of test assets N converge to infinity.

The proof is in the appendix. Following the same example above, the estimated parameter in the second pass regression is a good proxy for the consumption growth risk as long as the factor loadings of single factor regression (with consumption growth) is uncorrelated with the factor loading of the value factor, i.e., the FMP is not contaminated by other factors.

Note that the method we propose is the feasible FMP construction approach that can exclude the effect from factor 2. If we intend to exclude the effect of factor 2 by controlling factor 2, as shown in section 3.2, the FMP is still contaminated by factor 2.

Section 3.4 Issue with the time-series approach

Up to Section 3.3, we mainly discuss the cross-sectional method. We could also construct an FMP using the time-series approach. Following the regression (13), the time-series method also constructs an FMP for each factor independently. However, this approach remains exposed to several issues.

The classical time-series method only requires a small number of assets. This can lead to a breakdown of the assumption in Equation (25) since it is only reasonable for a large number of assets. Suppose the number of test assets (denoted by N, which is also the number of independent variables in regression (13)) is large. In real data, the sample size (T) in regression (13) is finite (for macroeconomic factors, the highest frequency is monthly, leading to roughly 600 months over 50 years. So T=500 in this case). Thus, there is an overfitting or an overidentification issue if N is close to or larger than T.

Even if we have a large enough sample size, we show in the proposition below that an FMP created by time-series method represents a combination of two risk factors.

Proposition 6: Let the true model be Equation (23). The regularity assumptions about measurement error and regression residuals are also satisfied as those in proposition 5. We estimate the coefficient in the following regression:

$$\tilde{\boldsymbol{f}}_{\boldsymbol{1}} = a + \boldsymbol{b}\boldsymbol{\Re} + \boldsymbol{u}, \tag{27}$$

where $\boldsymbol{\Re} = [\boldsymbol{R}^1, \cdots, \boldsymbol{R}^N] = [\boldsymbol{R}_{\boldsymbol{1}}; \cdots; \boldsymbol{R}_{\boldsymbol{T}}]$, with ";" the operator that stack row vectors,[12] and construct the FMP as $\frac{1}{N}\widehat{\boldsymbol{b}}'\boldsymbol{R}_{\boldsymbol{t}}$. When sample size and number of test assets both converge to infinity, the FMP constructed by the time-series method converges to $\frac{1}{N}\boldsymbol{\beta}_1^*\boldsymbol{V}^{-1}(a + \boldsymbol{\beta}_1^*\boldsymbol{f}_{1t} + \boldsymbol{\beta}_2^*\boldsymbol{f}_{2t})var(f_1)$.

The proof is in the appendix. As we can see from the proposition, the FMP still contains the other factor unless $\bar{E}(\frac{1}{N}\boldsymbol{\beta}_1^*\boldsymbol{V}^{-1}\boldsymbol{\beta}_2^*) \to 0$ as N goes to infinity. In a simplified scenario, $\boldsymbol{V}^{-1}$ is an identity. The expected value becomes $\bar{E}(\beta_1^{i*}\beta_2^{i*}) \to 0$. Since $\bar{E}(\beta_1^{i*}\beta_2^{i*}) = \bar{E}(\beta_1^{i*})\bar{E}(\beta_2^{i*}) + \overline{cov}(\beta_1^{i*}, \beta_2^{i*})$, even if the factor loadings are uncorrelated (equation (25)), we still require the

[12] Recall that $\boldsymbol{R}^i$ is a T by 1 column vector, $\boldsymbol{R}_{\boldsymbol{t}}$ is a 1 by N row vector, and $\boldsymbol{\Re}$ is a T by N matrix. With the definition of ";", the two expressions of $\boldsymbol{R}$ are equivalent.

cross-sectional average of factor loadings have mean zero. This is unlikely to be satisfied for most of the factors.

Section 3.5 Two-stage method for risk premium estimation

A fundamental goal in constructing an FMP is to test whether the non-traded factor is associated with a risk premium. Since the FMP is an excess return, Shanken (1992) shows that its average value is the risk premium. Another method is to refit a cross-sectional regression to estimate the risk premium. In this section, we show that, although these two methods are asymptotically the same in a large sample, the finite sample error that stems from the measurement error becomes smaller when we reapply a cross-sectional regression to test for a risk premium. Given that we apply the cross-sectional regression in the first stage to construct FMP, and apply the cross-sectional method again to estimate risk premium in the second stage, we call this the two-stage method (following Conner, Korajczyk, and Uhlaner (2015)).

Proposition 7: (1) As T converges to infinity, the average value of the coefficients in regression (26) converges to the true risk premium times a constant, i.e. $\frac{1}{T}\sum_{t=1}^{T}\hat{\lambda}_{1t} \to c\gamma_1$. (2) When T is finite, in the average value of the coefficients ($\frac{1}{T}\sum_{t=1}^{T}\hat{\lambda}_{1t}$), the finite sample error that comes from factor measurement error is in order of $O(\frac{1}{\sqrt{T}})$. (3) With the two-stage method, the finite sample error that comes from the factor measurement error in the estimated risk premium is in order of $O(\frac{1}{T})$.

The proof is in the appendix. If the measurement error for some non-traded factor is very large, it can lead to a large and noisy component in $\frac{1}{T}\sum_{t=1}^{T}\hat{\lambda}_{1t}$, the estimated risk premium in one-stage method. When we apply the two-stage method, the effect of measurement error becomes much smaller, which can lead to a smaller estimation error in a finite sample. Badduzi and Robbotti (2009) compare the average value method with the two-stage method (although the FMP is constructed by the time-series approach in their paper), and find that the two-stage method is superior. We provide one possible explanation for this finding. Conner, Korajczyk, and Uhlaner (2015) propose a two-stage method to estimate the risk premium because the method can reduce the Error-in-Variance bias. In this section, we show that a similar two-stage method can also reduce the effect of the measurement error in the estimated risk premium.

Note that in the testing stage, we should incorporate all factors to mitigate the issue of model specification. In this proposition, we only examine the scenario with the single-factor model in testing, but it is easy to extend it to the multifactor model. Also, note that two-stage method can only reduce the error from the measurement error. The error in the testing stage is still in order of $O(\frac{1}{\sqrt{T}})$. Thus, the method can be particularly useful for the factors with large measurement error, possibly including macroeconomic factors.

Section 3.6 Error-in-Variable (EIV) issues and the IV approach.

It is well known that cross-sectional regression analysis is subject to EIV bias in testing asset pricing models. EIV also affects the correlation between factor and FMP. To see this, suppose $\boldsymbol{\beta}$ is estimated with an error *v*, so $\widehat{\boldsymbol{\beta}} = \boldsymbol{\beta} + \boldsymbol{\nu}$. Then the true variance of the optimal FMP is larger than its estimated variance, that is,

$$\boldsymbol{w}'\boldsymbol{V}\boldsymbol{w} = [\boldsymbol{\beta}'\boldsymbol{V}^{-1}\boldsymbol{\beta}]^{-1} > \left[\widehat{\boldsymbol{\beta}}'\boldsymbol{V}^{-1}\widehat{\boldsymbol{\beta}}\right]^{-1}. \qquad (28)$$

The first equality is established through plugging in Equation (9) into the objective function of Equation (8). Because the variance of the FMP is reciprocal to the correlation between FMP and $\tilde{f}$ (Equation (7)), the correlation between the estimated FMP and the factor is empirically higher than its true value. Therefore, a method (such as the OLS method) that delivers a maximally correlated portfolio may not be the optimal choice unless the EIV problem is corrected.

EIV is also presented in the sorting-by-beta method. To construct FMPs, we first estimate factor loadings (betas) for each asset, then sort assets by their betas, and group the assets into portfolios by the sorted beta. FMPs are the difference between average returns of assets in the highest and the lowest beta groups. Because estimated betas contain estimation error, the larger (smaller) betas are more likely to produce a positive (negative) estimation error. In an extreme case, where a major part of the estimated betas is an error, the sorting-by-beta approach is tantamount to sorting by error. Thus, even if the factor does price assets in the cross-section, the difference in the average returns between the assets in the highest and the lowest estimated beta groups may not represent the difference of their risk exposures to the factor. The FMP created by this approach might not be well correlated with the original factor. Hence, the sorting-by-beta method, like the cross-sectional approach, suffers from an EIV bias.

IV approach can adjust for this issue. Assume that we want to test a K factor model or construct an FMP (in this case, $K = 1$). We divide the total sample into odd and even month subsamples. We run time-series regressions for the subsamples of odd and even months separately, thereby estimating independent odd and even months betas for each asset. With odd months betas as IV betas and even months betas as EV (evaluation variable) betas, we construct the matrices for betas of all assets: $\widehat{\boldsymbol{B}}_{\boldsymbol{IV}}$ and $\widehat{\boldsymbol{B}}_{\boldsymbol{EV}}$, where $\boldsymbol{B}$ is the matrix of $N \times (K+1)$ containing all the betas augmented by a vector of 1, that is, $\boldsymbol{B} = [\boldsymbol{1}, \boldsymbol{\beta}]$, where $\boldsymbol{1}$ is N by 1 a vector of 1.

Then we calculate a second-pass cross-sectional IV regression. At each even month, we run a 2SLS (two-stage least squares) regression, and the estimated risk premium can be written as[13]

$$\widehat{\boldsymbol{\gamma}}_{\boldsymbol{t}} = (\widehat{\boldsymbol{B}}_{\boldsymbol{IV}}{}'\widehat{\boldsymbol{B}}_{\boldsymbol{EV}})^{-1}\widehat{\boldsymbol{B}}_{\boldsymbol{IV}}{}'\boldsymbol{r}_{\boldsymbol{t}}. \tag{29}$$

Here, $\boldsymbol{r}_{\boldsymbol{t}}$ is the excess return for even months and is an N×1 vector. Correspondingly, at each odd month, we take the betas in the even months' subsample as the IVs and estimate the equation to obtain the risk premium.

When error contains no factor structure (section 3.1), Jegadeesh et al. (2019) shows that the IV approach can converge at the speed of $\sqrt{NT}$. When error contains a factor structure (Section 3.2 and later), Jagedeesh and Noh (2013) shows that the IV approach can converge at the speed of e^T, while classical OLS method can only converge at the speed of $\sqrt{T}$. Hence, in both cases, the IV approach can adjust for the EIV issue.

Section 3.7 Asset selection.

We propose to use a large number of test assets (such as individual stocks/bonds) for a reason described in Section 3.3 (Equation (24)). However, including more assets along can create issues if they are not correlated with the underlying factor. [14] For example, Gospodinov, Kan, and Robotti (2018) find that the estimated coefficients in a cross-sectional regression can be large and significant even if the factor is not priced. The IV approach can be used to select well-correlated

[13] We do not use the GLS-IV approach, because Roll and Ross (1994) find that only an OLS approach correctly economically interprets the coefficient. In addition, the covariance matrix of individual assets is not invertible when the number of assets is much larger than number of time periods.

[14] This is particularly important for time-series approach, as basis assets are usually the characteristic sorted portfolio returns. If these characteristics are not correlated with the macroeconomic risk, the basis asset can be uncorrelated with the macro factor.

assets because assets well correlated with the factor should have similarly estimated betas in the odd and the even samples. Thus, the sign of the IV and EV betas usually should be the same. On the other hand, assets that are not driven by the factors likely have very noisy returns, and, thus, the IV and EV betas would often have different signs. Therefore, we should select only assets that have $\hat{\beta}_{IV}{}'\hat{\beta}_{EV} > 0$, that is, retain only those assets with IV and EV betas having the same sign.

This selection criterion cannot escape the possibility that the IV and EV betas have the same signs due to the likelihood of random errors in the same direction. If this happens often, it will induce an attenuation bias in the estimated risk premium. However, our later simulation results show that the bias in the IV method is small (similar to that of the IV approach without this adjustment)[15].

For time-series method, when we apply it to many test assets, it is also useful to select the most correlated ones. In this paper, we incorporate a simple variable selection method—Lasso (least absolute shrinkage and selection operator) and examine its effect on FMP construction empirically.

Section 3.8 Horserace among methods

Based on the previous section, we propose our method as follows. First, we apply cross-sectional regression on a single factor model to adjust for factor contamination. Second, we apply IV method to mitigate the EIV issue. Third, we apply factor selection approach to select basis assets. Finally, we reapply cross-sectional regression method of all factors and FMPs to estimation risk premium. In simulation and empirical sections, we will compare the proposed approach with various other existing methods. These methods include the classical time-series approach, sorting by beta approach, and cross-sectional OLS approach,

[15] For FMPs constructed by time-series approach, Giglio and Xiu (2018) suggest use a large set of portfolio returns as predictors and apply regularization methods for mitigating the asset selection problem. In Internet Appendix B, we apply their approach to use principal components and a large number of portfolios to construct FMPs, and we find that the asset pricing performance of these FMPs are still not beyond FMPs by cross-sectional approach in empirical results. The reason is that it is hard to verify the large set of portfolios (and their PCs) can span the return space as individual stock returns. Overall, the time-series FMPs has advantages to track (predict) macroeconomic cycles (as shown in Lamont (2001)), but may not be the best choice for testing asset pricing models.

Lehmann and Modest (1988) introduce a WLS method to construct FMP. Instead of using identity matrix as in OLS approach, they suggest using the diagonal matrix consisted by the residual variances $\boldsymbol{\Omega^{-1}}$ from the first-pass time-series regression as weighting matrix.

Stein (1956) and James and Stein (1961) propose the shrinkage method to minimize RMSEs when at least three parameters are being estimated. Their shrinkage beta can be written as

$$\widehat{\boldsymbol{\beta}}_{\boldsymbol{Stein}} = \left(1 - \frac{(N-3)}{\|\widehat{\boldsymbol{\beta}}^*_{\boldsymbol{\delta}}\|}\right)\widehat{\boldsymbol{\beta}}_{\boldsymbol{new}} + \bar{\bar{\beta}}, \tag{30}$$

where $\widehat{\boldsymbol{\beta}}^*_{\boldsymbol{\delta}} = [\hat{\beta}^1_\sigma, \hat{\beta}^2_\sigma \ldots \hat{\beta}^N_\sigma]$, and $\hat{\beta}^i_\sigma = \frac{\widehat{\beta}^i - \bar{\bar{\beta}}}{\sigma^i}$, in which σ^i is the standard error of $\hat{\beta}^i$. Also, $\left\|\widehat{\boldsymbol{\beta}}^*_{\boldsymbol{\delta}}\right\| = \sum_{i=1}^N (\hat{\beta}^i_\sigma)^2$. $\bar{\bar{\beta}} = \frac{1}{N}\sum_{i=1}^N \hat{\beta}^i$ or the mean of $\hat{\beta}^i$. $\widehat{\boldsymbol{\beta}}_{\boldsymbol{new}} = [\hat{\beta}^1 - \bar{\bar{\beta}}, \hat{\beta}^2 - \bar{\bar{\beta}}, \ldots, \hat{\beta}^N - \bar{\bar{\beta}}]$.

Then the Stein-adjusted risk premium estimate is

$$\boldsymbol{\lambda_t} = (\boldsymbol{B'_{Stein}B_{Stein}})^{-1}\boldsymbol{B'_{Stein}R_t}, \tag{31}$$

where $\boldsymbol{B_{Stein}}$ is the matrix of $N \times (K+1)$ containing all the Stein shrinkage betas $\widehat{\boldsymbol{\beta}}_{\boldsymbol{stein}}$, augmented by a vector of 1.

Stein's method can reduce the mean-squared error of the OLS estimator through the reduction of the standard error. Hence, the FMP constructed by this approach will be less volatile.

We will compare both LM and Stein's approach with others in this paper. Note that for all these classical cross-sectional approaches, the convention is to run multifactor regression to create FMP, which will lead to factor contamination.

Section 4. Data

In this section, we describe the data and variables used in this paper. The summary of the descriptive statistics of these variables is reported in Table 1.

Section 4.1 Stock Return Data

Monthly individual stock returns are from CRSP. The data starts from January 1964 to March 2016 (627 months). Following the extant literature, we exclude stocks with prices less than 1 dollar or market capitalizations less than 6 million dollars. We also exclude stocks that have less than 60 continuous monthly returns. After these exclusions, 10,833 stocks remain in our sample; there are 2,850 stocks in an average month; the total observations are 1,784,351. The mean return of individual stocks over a risk-free rate (the one-month T-bill rate) is 1.012% per month, but the median is 0.44% per month, indicating that there are very large positive returns for individual stocks.

Section 4.2 Explanatory Variables

Four macroeconomic variables obtained from the Federal Reserve Bank of St. Louis Research Website (FRED) serve as our non-traded factors; (1) the growth in per capita consumption (DPCERAM1M225NBEA in FRED code), (2) the percentage change in the consumer price index (CPIAUCSL), (3) the percentage change in industrial production (INDPRO) and (4) the percentage change in the unemployment rate (UNRATE). Following Chen, Roll, and Ross (1986), we use innovations in these macroeconomic variables as factors. To measure innovations, we use the residuals from a first-order vector autoregression (VAR). It is also possible to use first difference as innovations. But as discussed by Boguth and Kuehn (2013), the first difference method is a more conservative specification for risk exposures. Moreover, the results are robust to first differences (unreported). We also study factors for bonds, such as the default spread and term spread, downloaded from Robert Shiller's website. For traded factors, we download from Kenneth R. French's website (excess market return, small-minus-large market capitalization, and high-minus-low book/market portfolio returns). To construct the time-series factor-mimicking portfolios, we obtain 25 portfolios formed on size and book/market, 10 industry portfolios from French's website, and four bond returns, which include 1-year, 5-year, and 10-year treasury bond yields, and Moody's seasoned Baa corporate bond yield from FRED.

We also examine other consumption related factors including the CAY factor (the ratio of consumption to aggregate wealth proposed by Lettau and Ludvigson (2001)) and the consumption volatility factor proposed by Boguth and Kuehn (2013). These factors are available from Martin Lettau's and Oliver Boguth's websites, respectively.

Section 4.3 Corporate Bond Return Data

For corporate bonds, we use transaction records in the Trade Reporting and Compliance Engine (TRACE). TRACE provides corporate bond intraday trading price, trading volume, and sell and buy indicators, etc. Our sample period is from August 2002 to June 2017. We follow Bai, Bali, and Wen (2019)'s data screening procedure and return estimation approach. The monthly corporate bond returns are computed from the average quoted price at the end of the current month, accrued interest, and coupon payment for a month divided by the average quoted price at the end of the previous month or the beginning of the current month. A bond's excess return is the difference between its computed total return and the risk-free rate, where the latter is proxied by the one-month Treasury bill rate. Our final sample consists of 331,728 observations, and the average cross-sectional excess return is 0.389%, which is comparable to Bai, Bali, and Wen (2019)'s sample. We include only bonds that have at least 30 continuous monthly returns;[16] 6421 bonds remain in our final sample.

As to the explanatory variables, we first consider the four non-traded macroeconomic factors. We subsequently add the default spread, the term spread, and the corporate bond market return. The default spread is the return difference between Moody's long-term corporate BAA-rated bonds and AAA-rated bonds. The term spread is the return difference between the ten-year and one-year treasury bonds. The monthly corporate bond market return is the equally-weighted average of corporate bond returns in our sample.

Section 5. Simulation

5.1 Simulation Procedure

In this section, we examine, in the finite sample, the magnitude of the factor contamination of FMPs constructed using methods described in section 3. This is done through simulations.[17] Following the same notation in Sections 2 and 3, an observed factor ($\tilde{f} = f + \varepsilon_f$) contains two parts. The first part, f_t, is the projection of the factor into space of excess return (we call it return related component of the underlying factor or return related factor), and the other part, ε_f, is the measurement error term that is uncorrelated with excess return. The goal of the simulation is to examine the effectiveness of FMPs constructed by various methods on extracting the factor in excess return (f_t) from an observed factor ($\widetilde{f_t}$). If it is effective, the FMP should be almost perfectly

[16] The results are robust using different windows.

[17] In addition to factor contamination, the existing method also suffers EIV bias when there is an estimation error in factor loadings as well as the basis asset selection. These issues are evaluated extensively in the literature of asset pricing test. Since the issues are similar for FMP construction, we defer the simulation on measurement error of beta loadings in the Internet Appendix A. We find that the FMPs constructed by IV methods can yield risk premium with bias less than 5%, but FMPs constructed by other methods suffer severe biased estimation on risk premium.

corrected with the underlying factor, and not correlated with another uncorrelated (orthogonalized) factor.

We use the four macro factors and Fama-French three factors in the return generating process. For the macro factors, we construct FMPs by the method described in section 3, i.e., we use single factor cross-sectional approach to construct FMP, and apply the IV method with asset selection in cross-sectional regression. We call it IV approach for simplicity. We demonstrate in Section 3 (in the large sample theories) and will show in this section (in the finite sample) that this method should deliver an FMP that will not contain measurement error and will not suffer factor contamination. Thus, the FMPs for macro factors are considered as the return related component of the macro factor in simulation. Since Fama-French three factors are traded factors, they contain no measurement errors. Their original factors are the same as the return related factors.

For return related component of each macro factor, we orthogonalize the other factors [18] to make them uncorrelated. For example, if we want to construct FMP for consumption growth, the other six factors are orthogonalized.[19] Orthogonalized factors are used for data generating process and examining factor contamination. If the FMP of the consumption growth factor is correlated with orthogonalized control factors, there is factor contamination because the FMPs contain the risk component that is in the orthogonalized control factors but not in the consumption growth factor. The vector of all factors (the return related macro factor and other orthogonalized factors) is denoted as $f_t^{\perp}$. We calculate the mean, variance and covariance (zero in this case) of the factors in $f_t^{\perp}$. These values are used for simulations.

We run the time-series regression for returns of each asset (R_t^i) on the orthogonal risk factors ($f_t^{\perp}$) to obtain beta loadings (B^i) and residual ε_{it}. Similar to orthogonalize factors, we orthogonalize the beta loadings of the seven factors, which is expressed as $B_i^{\perp}$. We orthogonalize the beta to satisfy the assumption in Section 3.3 (Equation (25)), in which we assume that the cross-sectional

[18] Note that we orthogonalize only return related factors, i.e. FMP constructed by IV method for macro factors and original Fama-French three factors.

[19] We adopt "Gram-Schmidt's orthogonalization process". Specifically, we regress the first control factor to consumption growth, and use the residual as the proxy for the orthogonalized first control factor. Then we regress the second control factor on the orthogonalized first control factor and the consumption growth factor, and use the residual term as the proxy for the orthogonalized second control factor. Following the same to other control factors, the resulting factor matrix have seven columns, and each column is orthogonal to other columns.

correlation between loadings of two factors converges to zero when N approaches to infinity, if the two factors are uncorrelated. In the real data, we find that for each macro factor, the cross-sectional correlations between its factor loading and the loadings of other orthogonalized factors are small. On average, it is 0.08. Therefore, the assumption is close to be true in the real data. We still orthogonalize loadings to make the correlations exactly zero. The mean, variance and covariance (zero in this case) of the loadings $B_i^{\perp}$ are calculated for simulations.

With these orthogonalized factors and loadings, we can proceed to the data generating process of asset returns in simulation. We first simulate orthogonalized factors using Monte Carlo simulations and keep the mean, variance and covariance of the factors the same as those from the data. For all simulated orthogonalized factors, we subtract the mean of these factors and then adding pre-specified true premia λ_0 set equal to observed the average risk premia from Chen, Roll and Ross (1986) and Chen and Kan (2003). The resulting factor is $f_t^{true} = f_t^{\perp} - \overline{f^{\perp}} + \lambda_0$. We also generate the factor loadings of all stocks for each factor from a multinomial normal distribution by keeping the same mean, variance and covariance from the real data. The simulated return is computed as $R_{it}^s = f_t^{true} B_i^{\perp} + \varepsilon_{it}^s$, where ε_{it}^s is simulated from a normal distribution by keeping the same mean and variance of ε_{it} from the real data. We have simulated the returns for each individual stock and the Fama-French 25 size and book-to-market portfolios.

Note that the orthogonalized factors are only used for data generating process, but these factors are not observable. Instead, the four macro factors and three Fama-French factors are observed. The return related component of these factors are correlated, and there are measurement errors for macro factors. Given that only observed factors are used to construct FMP, we need to simulate them. Since Fama-French three factors have no measurement errors, they are observed factors. For the four macro factors, there contain measurement errors. Hence, the simulated observed factor is constructed by adding the simulated return related factor an error term in simulation: $f_t^s = f_t + v_t$, where is extracted from a normal distribution with variance equals the variance of return related factor.[20] The return related factors, f_t, are simulated from a multinomial normal

[20] From the real data, the correlation between FMP_IV and the observed factor is close to 0.5. IF FMP_IV has no factor contamination, the correlation above implies that the variance of return related factor and measurement error is equal. Moreover, the results are robust if variance of measurement error is 5 times larger than that of return related factor.

distribution with the same mean, variance and covariance as those from the return related factors in the real data.

After simulating returns and observed factors with measurement errors, we apply various methods to construct FMPs for each macro factor.

- For the IV method (denoted FMP_IV), we firstly run single factor regression by regressing simulated return on each simulated observed factor to obtain the loading. Note this single factor contains measurement errors. Then we run cross-sectional regression by regressing simulated return on beta loadings to estimate coefficients in each month, based on the IV method and asset selection criteria introduced in section 3.
- For the OLS method (denoted by FMP_OLS), we firstly run multivariate regression by regressing simulated return on all seven simulated observed factors to obtain loadings. Then we run cross-sectional regression by regressing simulated return on the seven beta loadings to estimate coefficients in each month. Similarly, we can create FMPs using Lehmann and Modest (1988) and Stein (1956) method and denote them as FMP_LM and FMP_Stein, respectively. Note that all these classical methods run multivariate regression to construct FMP, which is the key reason for factor contamination. We can also construct FMP from a single factor regression using the above cross-sectional approaches, and they should also not suffer the factor contamination issue in a reasonable large sample. However, we choose only to apply single factor regression in IV approach for simplicity and for the consistency with the empirical analysis. Besides, there are other advantages of the IV approach. We defer the simulations to examine them in the Internet Appendix.
- For sorting-by-beta method, we firstly run multivariate regression by regressing simulated return on the seven simulated observed factors to obtain loadings. Then, we long the high beta group (top 20%) and short the low beta group (bottom 20%), and the difference between returns of high and low groups is FMP_SB.
- For the time-series approach, we regress the simulated observed factors on simulated returns of Fama-French 25 portfolios , and use the fitted value in each regression as FMP. These FMPs are recorded as FMP_TS. There are other choices of basis assets for FMP_TS, and they have similar results in simulations.

With these FMPs, we can evaluate whether they suffer factor contamination. To this end, we calculate the correlation between the FMP and corresponding return related component of the underlying factor, as well as correlations between FMP of one macro factor and other six orthogonalized factors. The factor contamination occurs if the FMPs capture components that are not in its underlying factor but in other factors. We iterate the simulation by 1,000 times and report the summary statistics of these correlations in Table 2.

5.2 Simulation results

Panel A in Table 2 reports the correlation between FMPs with their corresponding return related factors. We do not examine the correlation between FMP and the observed factor because their maximum correlation depends on the variance of the measurement error. Instead, the correlation between FMP and return related factor can have correlation equal to 1. Taking consumption growth as an example, the averaged correlation between FMP_IV and the true consumption growth factor is 0.999. Hence, FMPs constructed by the single-factor IV method have a nearly perfect correlation with return related component of the underlying factors. Therefore, IV approach has almost no factor contamination. The correlation between FMP_OLS and the return related component of consumption growth factor is 0.798. FMP_Stein has the same correlation with the return related factor as FMP_OLS because the Stein method only adds a scaling effect to the FMP_OLS. The averaged correlation between FMP_LM and the return related factor is 0.841, slightly higher than that for FMP_OLS. These cross-sectional methods (such as OLS, LM, and Stein) could not yield FMPs that have close-to-perfect correlations with return related factors because of the factor contamination from using multiple regression in the cross-sectional approach. Using univariate regression with asset selection method, the IV method alleviates these problems. The correlation between FMPs constructed by the sorting-by-beta method and the return related component of the consumption growth factor is 0.704. Time-series approach with Fama-French 25 portfolios as basis assets also has low correlations with return related factors. These two methods suffer the same contamination issues as for the cross-sectional approach, so the low correlations are expected.

Panels B and Panel C of Table 2 present the correlations between FMPs for each macro factor and other orthogonalized factors.[21] In the first column, we present the correlations for consumption

[21] The reason not to examine the correlation between FMP of one macro factor and the return related component of another macro factor (which is not orthogonalized) is shown below. Since the return related factors are correlated, for

growth factors. The results for other macro factors are shown in consecutive columns, and they are qualitatively similar. The FMPs of consumption growth (CG) have six correlations coefficients with other six orthogonalized factors. We report the maximum value and the average value across the six correlation coefficients in each simulation in Panels B and C, respectively. Panel B lists the average values of the maximum value across 1,000 simulations. Panel C lists the mean values of the recorded average value across 1,000 simulations. Consistent with analysis in Section 3, we find that the IV method (with univariate regression and asset selection) produces almost zero factor contamination. In comparison, all FMPs constructed by other methods lead to factor contamination. For example, the maximum correlation between FMP_SB for consumption growth and the other six control risk factors can be 0.119.

Overall, these simulation results testify that the commonly used FMP construction methods (sorting-by-beta, time-series, and multivariate cross-sectional) suffer from factor contamination. The method we propose (the IV method in a univariate cross-sectional analysis with asset selection) yields almost perfect correlation with the return related component of the underlying factor and contains the minimal factor contamination.

Section 6. Examine the FMP in the data

From this section, we evaluate whether FMPs constructed by various methods empirically satisfy the three FMP selection criteria. We focus on the FMPs for the four macro factors and augment this by examining the FMPs for traded factors (Fama and French three factors) for comparison[22]. To examine these FMPs, we explore several criteria:

(1) FMPs are correlated with the underlying factors,

any macro factor, the correlation between its FMP and other return related factor is not zero. But the non-zero correlation is capturing component of another factor that is also part of the underlying macro factors. E.g., let consumption growth and market returns be correlated risk factors. If FMP of consumption growth factor is perfectly correlated with the return related component of the factor (implying that the FMP is not contaminated by other factors), it is still correlated with market return. However, this nonzero correlation does not indicate that the FMP contains the risk that is not correlated with consumption growth. Suppose that the FMP of consumption growth is correlated with the orthogonalized market return, then the FMP captures the risk not belonging to the consumption growth. In this case, the FMP is contaminated.

[22] We also test the robustness by using alternative traded factors, such as Carhart 4 factors, Fama-French 5 factors, and Fama-French 6 factors. We find these results are robust to these specifications. In some cases, we have to drop the market factor to achieve robust results due to the strong correlation between the FMP of consumption growth and the market factors. Theoretically, consumption growth and market factor should represent similar risk.

(2) FMPs are correlated with the systematic risk of returns,

(3) FMPs explain the cross-sectional of mean returns.

Intuitively, an FMP should represent the risk of the underlying factor, as shown in the constraint of the least mispriced theory. Besides, if the underlying factor is a true risk factor, systematic risk should be correlated with FMP returns. If the factor can price assets in cross-section, the FMP should also price all assets. Our three criteria are studied sequentially in Sections 6.1 to 6.3. We provide some robustness checks by adding several other consumption-related factors in Section 6.4.

Section 6.1 First Criterion: Correlation with Underlying Factors

An effective FMP should correlate significantly with its underlying non-traded factor so that the FMP contains similar risk information. In unreported results where we estimate correlation for the whole sample period, all of the correlations between FMPs and their underlying factors are significant at 1% level, thereby suggesting that all the FMPs satisfy this criterion.[23] However, the observed significance may be driven by the large sample size and possibly by non-stationarity. Correlations between FMPs and underlying risk factors could be spuriously inflated by time variation in the mean returns. To examine this possibility, we divide the full sample into five subsamples roughly by decades and compute subsample correlations. Table 3 lists the average value of the correlation coefficients in the five subsample and the number of significant correlation coefficients in the five subsamples at 1% significance level.

Although the correlations for cross-sectional and sorting-by-beta methods are all statistically significant, their magnitudes vary across FMPs. Notably, the correlation between FMPs constructed by the IV method (FMP_IV) and the underlying factors are smaller than those from the OLS method. The correlation between FMP_IV for consumption growth and the underlying consumption growth factor is 0.411, but the correlation between FMP_OLS for consumption growth and the underlying consumption growth factor is 0.636. However, as discussed in Section

[23] Although there is no well-accepted threshold of correlations that an effective FMP should satisfy, the correlation should be significantly different from zero to avoid the "useless factor" problem (Barillas et al., 2017). The requirement of significant correlation avoids selecting the wrong model setting for the time-series approach. For example, if the R square from a time-series is very low (such as 0.05), the basis assets have virtually no relation with the factors.

3.6, OLS-based FMPs are subject to substantial EIV issue, overstating sample correlations with its factors.

For the time-series approaches, we find that most of them are uncorrelated with the factors in most sub-periods. For instance, the correlation is only significant in one sub-period for consumption growth FMP constructed, which illustrate that the FMPs by time-series approaches are weakly related to their underlying factors. Since the different sets of basis assets are likely to be different in their correlation with underlying macro factors, the choice of the basis assets is essential. For example, unexpected inflation can be related to bond returns; therefore, basis assets that have bond as a component (Lamont approach) are likely to be correlated with this factor. Our result confirms this conjecture as for four out of five decades, the correlations between FMP_time-series and CPI are significant. Correlations between time-series FMPs and underlying factors is also lower than that for cross-sectional FMPs. For example, with the industrial production factor, the correlation of a time-series approach is 0.293 while it more than doubles to 0.789 for a cross-sectional approach (OLS). Such a striking difference emphasizes again how FMPs can be method dependent. Compared with FMPs for non-traded factors, FMPs for the Fama-French factors have strong correlations with their underlying risk factors in most cases. Due to similarities across various approaches, FMPs are likely less advantageous for traded factors.

[Table 3 around here]

Section 6.2 Second Criterion: Correlation with the systematic risk of returns

An FMP should be correlated with the systematic part of returns. Following Pukthuanthong et al. (2019), we apply the asymptotic approach of Connor and Korajczyk (1988) (CK) to extract ten principal components from the equities return series. The principal components of covariance matrix of returns represent the systematic part of asset returns. We then compute canonical correlations between the ten CK principal components and the factor candidates and test the significance of these canonical correlations by the chi-squared statistic.

We examine this criterion for FMPs that are constructed by various methods, and also for their corresponding original factors as a comparison. The four original macroeconomic factors are those we have already considered above, CG, CPI, IP, and UE. The original traded factors are the three Fama-French factors (MKT, SMB, HML). To examine this criterion, two conditions have to be satisfied. We assume that a FMP strongly satisfies this criterion if it significantly related to any canonical variate in all decades or has a mean *t*-statistics in the second row of each panel in Table 4 exceeding the one-tailed, 2.5% cutoff based on the chi-squared value and also has an average number of significant decade *t*-statistics exceeding 1.75 (bottom row of each panel.)[24]

[Table 4 about here]

Notably, the four original macro factors do not pass whereas the thee FF factors pass this criterion. FMPs constructed by all of the cross-sectional methods and the sorted beta method satisfy the second criterion. For FMP_time-series, none of the macro factors satisfies and thus the time series approach does not pass the second criteria.

Section 6.3 Third Criterion: Risk Premium Estimation Using FMPs

This section compares the extent to which various construction methods for FMPs produce different risk premium estimates.

Cross-Sectional Approaches

Table 5 reports risk premium estimates using instrumental variables and other cross-sectional methods for obtaining FMPs. We select stocks whose betas in odd and even months have the same signs in order to select assets that are well correlated. Only 463 (about 4.6%) of more than 10,000 stocks are not used to construct any FMPs, with each factor using about 6,000 stocks.

The results show that risk premium estimated by different methods often have dramatic disagreements, in both magnitude and significance. For example, the risk premium for consumption growth is 0.066 (T-value=2.202) using OLS while it is 0.164 (T-value=3.238) using IV. Despite the fact that LM and Stein partly resolve the OLS downward bias, the risk premium for consumption growth with these two methods are still much smaller than those in IV. With OLS, LM, and Stein, the risk premium estimates for industrial production and unemployment are negative and positive, respectively, which are opposite to theoretical prediction[25] and contrast markedly with the IV estimates. The risk premium for the unemployment rate should be negative

[24] Pukthuanthong et al. (2019) require an average number of significant decade t-stat exceed 2.5 from 10 factor candidates. We have seven factor candidates, thus 1.75 is from using the same proportion as theirs. The reason is as follows: “This is a conservative threshold to ensure we do not miss a true factor at our necessary condition stage. We focus on the significant canonical correlations, rather than all canonical correlations, because insignificant CCs imply that none of the factors matter, so using them would be over-fitting.”

[25] A similar result is obtained by Giglio and Xiu (2018). As a robustness check, we drop the FMP for industrial production factor since it is not significant, and we find that the results for the other FMPs are virtually unaltered.

because stocks with a positive unemployment beta can be viewed as hedging to economic downturns. Stocks with a negative unemployment beta are riskier because the returns for these stocks decrease during periods of high unemployment.

For comparison, we estimate risk premium for the three Fama-French (FF) traded factors. The signs and significance levels for risk premium estimates do not vary much across methods. Hence, EIV seems to be less of a problem for traded factors.

As revealed in the bottom five lines of Table 5, the IV-based risk premium of macro factors are still significant, even after including the three FF factors; this is not true for the other FMP construction methods.[26] Moreover, the risk premiums for the FF factors are virtually the same with any of the FMPs added into the estimation. This is somewhat curious because it suggests that the FF factors do not contain the same information as the macroeconomic factors. One might very well wonder what risks the FF factors do represent.

Time-series approach

Under the time-series approach, we perform risk premium estimation with FMP constructed by Lamont (2001) method. Compared with the IV and OLS approaches, the estimated risk premium for consumption growth is negative and insignificant, while the risk premium for industrial production is significantly negative. However, the time-series method works well for the Fama-French three factors. Specifically, it produces a similar statistical significance for the risk premium estimates of three factors.

As discussed earlier, a time series construction method for FMPs can be effective if the basis assets are correlated with the factors (Lewellen, Nagel, and Shanken, 2010). The basis portfolios in Lamont (2001) includes a market return, which is one of the three Fama-French factors. Lamont's industry-sorted portfolio returns might very well be correlated with the FF SMB and HML factors. Thus, the Lamont method can be an effective FMP for estimating Fama-French risk premium, although FMP is not normally applied to traded factors. Correlations between macro factors and

[26] We note that a negative risk premium for unexpected inflation is to be expected (see Boudoukh and Richardson, 1993); high unexpected inflation has a downward impact on stock prices. Stocks with a positive inflation beta hedge inflation risk; they have higher returns in periods of high inflation while stocks with a negative inflation beta are riskier because their decrease during periods of high inflation.

Lamont basis assets are low; thus the Lamont method is probably not very effective for FMP construction of macro factors.

Sorting-by-Beta Approaches

For sorting-by-beta method, we estimate betas from time-series multivariate regressions and then sort the betas for each factor into ten equally-weighted deciles. We then construct FMPs as the average return in the highest decile minus the average return in the lowest percentile (High-minus-Low). The FMPs are used as factors to estimate risk premium, which is reported in the table. For macro factors, the estimated risk premiums are insignificant, especially when Fama French three factors are included. This is consistent with our conjecture that the FMP constructed by sorting-by-beta method can attenuate the variation in returns among stocks with different sensitivities to the factor when measurement error in beta is large.

[Table 5 about here]

Section 6.4 Robustness with Respect to Other Consumption-related Factors

Previous literature finds little relation between asset returns and consumption-based factors, probably because of the large noise of consumption growth.[27] However, we find that the risk premium for consumption growth is significant when using its associated FMP. Rather than focusing on the measurement problem of consumption growth, Lettau and Ludvigson (2001) derive a conditional consumption CAPM, which can explain average stock returns in the cross-section, using the consumption-wealth ratio (CAY) as a conditioning variable.

Table 6 reports estimated risk premia when adding the CAY factor.[28] In all but one specification, CAY factor is associated with a negative risk premium and is always insignificant. Consumption growth factor has a significantly positive risk premium for the IV FMP, the OLS FMP, and weakly significant at 10% for sorting beta. This is consistent with our earlier results that use four macroeconomic factors. Following Lettau and Ludvigson (2001), we include an interaction term between CAY and consumption growth; its risk premium is insignificant. CG remains significant

[27] Indeed, we also find that the risk premium for consumption growth is insignificant if we use raw consumption growth rather than its FMP (unreported).

[28] In Appendix Table 1, we report analogous results using all four macro factors (CG, CPI, IP, and UE). The IV results are robust to this alternate specification. As shown there, results for time-series based approaches are not robust. Correlations with underlying non-traded factors differ dramatically and so do their risk premium estimates.

at 5% for IV and 10% for OLS and sorting beta. When we include three FF factors, CG is significant at 5% for IV but not significant for other approaches.

[Table 6 about here]

Boguth and Kuehn (2013) find that consumption volatility, supposedly a proxy for macroeconomic uncertainty, is also a source of risk and has a negative risk premium. In unreported results, we also add consumption volatility as a control variable. We find that the risk premium of the consumption volatility factor is negative but insignificant in all specifications across all FMP construction methods. In contrast, the risk premium for consumption growth is still significant. Therefore, using FMPs of consumption growth, our results confirm that consumption growth is a robust risk factor that can explain the cross-sectional stock returns conditional on other consumption related factors.

Our overall conclusion for US equities is that FMPs constructed by the IV approach satisfy all our criteria. Moreover, the IV-based FMPs dominates FMPs constructed by other methods in producing larger and more significant risk premium estimates. With the IV method, consumption growth, inflation, unemployment rate, and three Fama-French factors can explain cross-sectional stock returns.

7. Test Risk Premium in Corporate Bonds Market by Using FMPs

Bond returns are associated with macroeconomic factors since bonds are related to firms' fundamentals that are affected by business cycle (Ludvigson and Ng, 2009). Fama and French (1993) propose two non-traded bond factors, the default and term spread. Gebhardt, Hvidkjaer, and Swaminathan (2005) find that the default spread significantly explains cross-sectional bond returns even after controlling for bond characteristics such as duration and rating. In contrast, Bai, Bali, and Wen (2019) find that attributes such as value-at-risk and rating dominate default and term. Bessembinder et al. (2008) suggest that a broad bond market return, unexpected GDP growth, and unexpected inflation explain excess abnormal bond returns. Following these papers, we evaluate the FMPs for four macroeconomic factors, a broad bond market return (MKT_B), and the default spread (DS) and term spread (TS).

We use various FMP construction methods: IV, OLS, LM, Stein, time-series, and sorting-by-beta. Following the criteria, we first analyze correlations between FMPs with their underlying factors

(1^{st} criterion) and with the principal components of covariance matrix of individual corporate bond returns (2^{nd} criterion). The results are similar to those for equities. Panel A of Table 7 shows that all the FMPs have strong correlations with their underlying factors; thus, all approaches satisfy the first criterion. Unlike the previous test of the first criteria where we present correlations for each decade, we present the correlation of FMPs and underlying factors for the whole sample period due to shorter time series (from 2002 to 2017). Our sample period is consistent with that in Bai, Bali, and Wen (2019). Panel B examines whether the FMP is correlated to the systematic risk of bond returns. FMPs constructed by all approaches except time-series approach pass this criterion. We focus only on one criterion (the t-stat of significant canonical correlation) because our sample period for bond is only a decade. For the time-series approach, only consumption growth and shock in CPI pass.

Panel C presents the results of estimating the risk premium for corporate bond return in a similar vein as that for equity returns. The time-series method (Lamont approach) produce significant risk premiums. For IV-based FMPs, consumption growth, industrial production, bond market return, and default spread pass, and have the signs of risk premium consistent with the theory. Risk premium associated with Stein, LM, or OLS FMPs are insignificant. Interestingly, the time-series method (Lamont approach) produce significant risk premiums, but with counterintuitive signs for consumption growth, industrial production, and unemployment. The first two should be positive while the last should be negative. Theoretically, positive consumption growth and industry production shocks are associated with strong firm fundamentals, suggesting a positive bond return. Since Lamont (2001) uses stock portfolio returns as basis assets to create time-series FMPs, the negative sign might reflect the negative correlation between stock returns and bond returns. In an untabulated result, we use portfolios constructed by bond returns as the basis assets with time-series approach. The risk premiums of macro factors above are positive but insignificant, when we control for other traded factors.

[Table 10 about here]

Section 8. Conclusion

A voluminous literature applies factor-mimicking portfolios to convert non-traded factors into their traded versions, and then to estimate risk premium. However, no studies summarize and demonstrate that indeed, there are quite a few ways to construct FMPs, and each methodology has pros and cons for testing underlying factor. The performance of FMPs depends on the way we construct FMPs and the basis assets we use to construct them. Our paper proposes a new economic explanation of FMP, delves into the issues for existing method and offers a new method for FMP construction. We also examine FMPs using three necessary conditions.

Simulation results show that all other existing methods suffer factor contamination, while our method has almost no factor contamination. Empirically, we apply our IV method to estimate risk premiums for a series of non-traded factors. We firstly construct factor-mimicking portfolios from four classical macroeconomic factors using the IV approach and find that the non-traded versions of consumption growth, CPI, and unemployment rate have significant risk premiums in stock market. The conclusion cannot be obtained from the same factors constructed by the extant mimicking portfolios approaches. We also find that the factor-mimicking portfolios for the three factors correlate to their corresponding factors and covariance of asset returns, thereby passing the FMP criteria we propose. We also apply our method to estimate risk premium in the corporate bond market and find that consumption growth and industrial production price corporate bond returns with positive risk premiums.

Table 1. Descriptive Statistics

This table reports the summary of statistics on the main variables, in which we list the number of observations, mean, median, standard deviation, and percentiles (1st, 5th, 25th, 75th, 95th, and 99th). Panel A reports the statistics for excess stock returns and its explanatory variables. For the stock return, we have 10,833 stocks in total and 626 months data. The stock returns are over a risk-free rate (one-month T-bill rate). The explanatory variables includes, consumption growth rate (CG), consumer price index (CPI), industrial production (IP), unemployment rate (UE), excess stock market return (MKT), small-minus-big size portfolio (SMB), high-minus-low book/market portfolio (HML) and the consumption to wealth ratio (CAY). Panel B lists the statistic for corporate bond returns and its explanatory variables. For corporate bond returns, we have 6,421 bonds and 179 months data. The bond returns are over a risk-free rate (one-month T-bill rate). In addition to the four macro variables (CG, CPI, IP, UE), bond market excess return (MKT_Bond), default spread (DS) and term spread (TS) are taken as explanatory variables as well. MKT_B is the equally weighted return of all corporate bond return in our sample in excess to risk-free rate. DS is a default spread, measured by the return difference between Moody's long-term corporate BAA-rated bonds and AAA-rated bonds. TS is a term spread, measured by the return difference between ten-year treasury bond and one-year treasury bond. The sources of these data are described in detail in Section 3.

Panel A: Statistics for stock returns and its explanatory variables

Table 2. Simulation

This table shows the simulation results of the effectiveness of FMPs constructed by various approaches as a proxy of true risk factors. We generate simulated factors using return related factor added by a normally distributed measurement error. We generate simulated returns using orthogonalized true risk factor multiplied by orthogonalized true beta loadings. With the simulated return and simulated risk factors, we construct FMPs using six methods described in Section 5. The detail on the simulation is in Section 5. Panel A shows the correlations between FMPs and return related component of the underlying factors. Panel B presents the maximum correlations between FMPs for a macro factor with other factors. Panel C presents the averaged correlations between FMPs for a macro factor with other factors. The values in each table are mean values across 1,000 simulations. The sample period is January 1964 to March 2016. To be included, individual stocks must have at least 60 continuous monthly returns on CRSP. The macro factors include unexpected consumption growth (CG), unexpected changes in the CPI (CPI), unexpected changes in industrial production (IP), and unexpected changes in the unemployment rate (UE).

Panel A: Correlation between FMPs and their corresponding true risk factors

	CG	CPI	IP	UE
FMP_IV	0.999	0.996	0.986	0.988

Table 3: Summary Statistics of FMPs and their Correlations with the Underlying Factors

This table presents the mean, standard deviations of FMPs constructed by different approaches, as well as their correlations with the underlying factors. Panel A reports correlations between FMPs and their underlying factors across five subsamples, one of which spans a decade. The first row in Panel B is the mean correlation and the second row (# Sig) contains the number of subsample correlation that is significant at the 1% level (maximum of 5.) Panel B shows the means of the FMPs, and Panel C shows their standard deviation. We compare FMPs constructed by different methods: the FMP constructed by the IV approach in cross-sectional regression (FMP_IV), the FMP constructed by the OLS approach in cross-sectional regression (FMP_OLS), the FMP constructed by Lehmann and Modest's method (FMP_LM), the FMP constructed by Stein's method (FMP_Stein), the FMP constructed by time-series regression with Lamont portfolios as basis assets (FMP_Time-series), and the FMPs constructed with the sorting by beta approach (FMP_SB).

Correlation with Original Factors across Five Decades

Table 4. Correlations with the Systematic Risk of Returns

This table reports canonical correlations between FMPs and Principal Components of the covariance matrix of individual stocks. The factor candidates include FMPs constructed using the methods of IV, OLS, Lehman, and Modest (1999), Stein, and Lamont (2001). As comparison, we also include the canonical correlation results for the original risk factors. The principal components (PCs) are extracted as explained in Pukthuanthong et al. (2019) using the Connor and Korajczyk (henceforth CK, 1988)'s cross-sectional method. We summarize significance levels for factor candidates. The following procedure is implemented to derive the significance levels of each factor candidate: First, for each canonical pair, the eigenvector weights for the 10 PCs are taken and the weighted average PC, (which is the canonical variate for the 10 PCs that produced the canonical correlation for this particular pair) is constructed. Then, a regression using each CK PC canonical variate as the dependent variable and the candidate factor realizations as 7 independent variables is run over the sample months. The t-statistics from the regression then give the significance level of each candidate factor. There are 10 pairs of canonical variates in each decade and a canonical correlation for each one; thus, there is a total of 50 such regressions (10 regression per decade). The 1st row presents the mean t-statistic over all canonical correlations. The 2nd row reports the mean t-statistic when the canonical correlation itself is statistically significant. Rows #3 reports the average number of significant canonical correlation over the five decades. Critical rejection levels for the T-Statistic are 1.65 (10%), 1.96 (5%), and 2.59 (1%). We assume that an FMP satisfies this criterion if (1) it is significantly related to any canonical variate in all decades or that has a mean *t*-statistic in the second row that exceeds the one-tailed, 2.5% cutoff based on the chi-squared value, and (2) has an average number of significant *t*-statistics exceeding 1.75 (the 3rd row of each panel). *t*-statistics breaching the 5% (1%) critical level are in boldface (boldface and italics). The factors that pass necessary condition are in grey highlight.

Table 5. Risk Premia in Equity Market by using Factor-Mimicking Portfolios

This table reports risk premia estimates using Fama-MacBeth regression. For cross-sectional methods, we assume betas are constant. For the IV method, we use betas in even month as instruments for betas in odd month and apply the IV method with sample adjustment (IV*) to obtain FMPs. Then, we apply IV method for a second time to test risk premium of these FMPs (IV). For other methods, such as OLS, Lehmann, and Modest (LM), and Stein, we apply the corresponding approach (OLS, LM, Stein) to obtain factor-mimicking portfolios, and use these methods to run Fama-MacBeth regression again to test risk premium. For time-series approach, we use time-series to create FMPs and then estimate the risk premia for these FMPs using OLS method in the second pass regression. For sorting-by-beta method, we estimate betas from time-series multivariate regressions and then sort the betas for each factor into ten deciles. We then construct FMPs as the arithmetic average returns in the highest decile minus the average in the lowest percentile (High-minus-Low). The FMPs are used as factors to estimate risk premium, which is reported in the table. The sample period is January 1964 to March 2016. We use individual stocks that have at least 60 continuous month returns in CRSP. The risk factors include four macroeconomics variables, the consumption growth rate (CG), unexpected CPI changes (CPI), unexpected changes in industrial production (IP), and unexpected changes in the unemployment rate (UE). MKT is the excess market return (proxy by the value-weighted return of all CRSP firms in the US), SMB is the FF small-minus-big size factor, and HML is the FF high-minus-low book-to-market factor. The values in parentheses are T-statistics. *, **, and *** indicate significance at the 10%, 5%, and 1% level, respectively.

Table 6. Estimated Risk Premia with FMPs for Consumption Growth and an Alternative Consumption-Related Factor (CAY)

Here are estimated risk premia for consumption growth and the CAY factor of Lettau and Ludvigson (2001) and with and without three Fama-French (FF) factors. CAY is the log ratio of consumption to aggregate wealth. FMPs are constructed for each factor using three methods (IV, OLS, and sorting-by-beta (OLS-SB)). CG is the unexpected consumption growth rate. MKT is the excess market return, SMB is the FF small-minus-big size factor, and HML is the FF high-minus-low book-to-market factor. We obtain the monthly CAY from Martin Lettau's websites. The monthly sample is from January 1964 to March 2016. The t-values in parentheses are based on Newey-West standard errors. *, **, and *** indicate significance at the 10%, 5%, and 1% level, respectively.

Table 7. Testing FMPs to Explain Individual Corporate Bonds Returns

This table shows the four criterion tests to FMPs constructed by various approaches and with individual corporate bond returns as basis assets. Panel A reports correlations between FMPs and underlying factors for explaining corporate bonds. Panel B presents canonical correlations of FMPs with systematic risks using the same approach as that reported in Table 4 for equities. Panel C shows risk premia for corporate bond returns estimated with FMPs as factors. Panel D examines the fourth criteria of time-series approach where the FMPs are constructed from 10 randomly chosen FF portfolios (FF_random) and 10 portfolios formed from randomly chosen individual stocks (individual_random). The factors as described in Table 1. The sample period is August 2002 to June 2017. The numbers in parentheses are T-statistics. *, **, and *** indicate significance at the 10%, 5%, and 1% level, respectively.

Appendix Table 1: Combing Macro Factors and CAY

This table shows the FMP identification when combing the four macro factors with the CAY factor, which supplements the analysis in Table 10. Panel A shows the average correlations in five subsamples between FMPs and their underlying factors, and the number of significant correlations (# Sig) at 1% significance level in five subsamples similar to Panel A in Table 3 (first criteria). Panel B shows the canonical correlations between FMPs and the principal component of the covariance matrix of asset returns (the second criteria). The detail is described in Table 4. Panel C shows the estimated risk premia by using FMPs (the third criteria). The details of each method are described in Table 1.
